Laboratory Medicine
NOTICE

Medicine is an ever-changing science. As new research and clinical experience broaden our knowledge, changes in treatment and drug therapy are required. The authors and the publisher of this work have checked with sources believed to be reliable in their efforts to provide information that is complete and generally in accord with the standards accepted at the time of publication. However, in view of the possibility of human error or changes in medical sciences, neither the authors nor the publisher nor any other party who has been involved in the preparation or publication of this work warrants that the information contained herein is in every respect accurate or complete, and they disclaim all responsibility for any errors or omissions or for the results obtained from use of the information contained in this work. Readers are encouraged to confirm the information contained herein with other sources. For example and in particular, readers are advised to check the product information sheet included in the package of each drug they plan to administer to be certain that the information contained in this work is accurate and that changes have not been made in the recommended dose or in the contraindications for administration. This recommendation is of particular importance in connection with new or infrequently used drugs.
To Susan, with love
Key Features of Laboratory Medicine

A complete full-color guide to selecting the correct laboratory test and accurately interpreting the results—covering the entire field of clinical pathology

- 46 laboratory methods presented in easy-to-understand illustrations which include information on the expense and complexity of the assays
- Features an easy-to-follow, consistent presentation for each disease discussed
- More than 200 tables and full-color algorithms encapsulate important information and facilitate understanding
- Full-color blood-smear micrographs demonstrate common abnormal morphologies of red blood cells
- Valuable learning aids in each chapter, including learning objectives, chapter outlines, and a general introduction
- Extensive table of Clinical Laboratory Reference Values showing the conversions between U.S. and SI units for each value
- An essential text for medical students and residents studying clinical pathology, medical technology students, and for practitioners working in a clinical setting
- This edition has been enhanced by coverage of genetic test options that are now commonly used in clinical practice.

Blood-smear micrographs demonstrate common abnormal morphologies of red blood cells
200 tables and full-color algorithms encapsulate important information

CHAPTER 22

Hyperthyroidism

Hyperthyroidism is a clinical condition caused by excessive production of thyroid hormones. Symptoms of hyperthyroidism include increased heart rate, palpitations, heat intolerance, weight loss, diarrhea, and emotional lability. Other signs and symptoms may include hair loss, muscle cramps, and menstrual irregularities.

Thyroid Storm

Thyroid storm is a life-threatening emergency that occurs in patients with hyperthyroidism and may be precipitated by stress or infection. Symptoms include tachycardia, agitation, confusion, and fever. Treatment involves administration of beta-blockers, antithyroid medications, and fluid resuscitation.

Hypothyroidism

Hypothyroidism is a condition characterized by decreased levels of thyroid hormones. Symptoms of hypothyroidism include fatigue, weight gain, cold intolerance, and depression. Treatment involves the administration of thyroxine (levothyroxine).

Diagnosis of Hyperthyroidism

The diagnosis of hyperthyroidism is based on a combination of clinical findings and laboratory tests. Laboratory tests include measurement of thyroid-stimulating hormone (TSH), free thyroxine (T4), and triiodothyronine (T3). An elevated T3 level in the presence of a suppressed TSH level is indicative of hyperthyroidism.

Management of Hyperthyroidism

The management of hyperthyroidism involves treatment of the underlying cause and symptomatic management. Treatments may include antithyroid medications, radioactive iodine, or surgery.

Breast Cancer

Breast cancer is a malignant tumor that develops in the cells of the breast. It is the most common cancer in women and the second leading cause of cancer deaths among women. Risk factors for breast cancer include age, family history, and genetic factors.

Prevention

Regular mammograms, routine clinical breast examinations, and breast self-examination are important preventive measures for breast cancer.

Screening

Breast cancer screening can help identify tumors at an early stage, allowing for earlier treatment and better outcomes. Screening options include mammograms, breast MRIs, and ultrasound.

Treatment

The treatment for breast cancer depends on the stage of the cancer and personal preferences. Options may include surgery, radiation therapy, chemotherapy, hormonal therapy, and targeted therapies.

Cancer Prevention

Lifestyle factors that can help reduce the risk of breast cancer include maintaining a healthy weight, engaging in regular physical activity, limiting alcohol consumption, and avoiding smoking.

Cancer Screening

Breast cancer screening is recommended for women aged 50-74 years. Mammograms are the primary screening tool, but women with a strong family history or other risk factors may benefit from more frequent screening.

Cancer Treatment

The treatment for breast cancer depends on the stage, type, and grade of the cancer, as well as the patient's age and overall health. Options may include surgery, radiation therapy, chemotherapy, hormonal therapy, and targeted therapies.

Cancer Prognosis

The prognosis for breast cancer is dependant on several factors, including the stage, type, and grade of the cancer, as well as the patient's age and overall health. Early detection and treatment can improve prognosis, while advanced-stage tumors may require more aggressive treatment options.

Cancer Support

Support and resources are available to help women and their families navigate the challenges of breast cancer. These may include support groups, counseling, and financial assistance.

Alison Woodworth, PhD
Assistant Professor, Medical Director of Esoteric Chemistry, Department of Pathology, Microbiology, and Immunology, Vanderbilt University Medical Center, Nashville, Tennessee
In the early 1990s when I was at the Massachusetts General Hospital as director of clinical laboratories, I was invited by Ramzi Cotran to join him and Stan Robbins at the Brigham and Women's Hospital for a meeting. In that meeting, they indicated to me that the Robbins Pathologic Basis of Disease, primarily an anatomic pathology book, would greatly benefit from a parallel book in clinical pathology (laboratory medicine). At that time, areas such as coagulation and toxicology were expanding rapidly with new disorders and new tests to diagnose them. Because there was little anatomic pathology in these fields, the discussions of these major areas of diagnostic medicine in the Robbins book were limited. In addition, as the test menu in the clinical laboratory was growing in complexity and cost, many important clinical laboratory tests for common disorders, such as the troponin test for myocardial infarction, were also discussed only briefly in the Robbins book. Both Robbins and Cotran understood that a discussion regarding the threshold for diagnosis of myocardial infarction, as troponin testing rapidly evolved and improved, was necessary to fully discuss the topic. There were many twists and turns from that meeting about 20 years ago to the development of this second edition of Laboratory Medicine: The Diagnosis of Disease in the Clinical Laboratory in the prestigious Lange series by McGraw-Hill. With this second edition, I believe we truly have a book that is essential for education of medical students and residents studying clinical pathology, and importantly, for practitioners in a clinical setting. By selecting the correct tests and interpreting the results correctly, physicians using this book should be able to optimize patient outcomes and reduce the cost to achieve a diagnosis.

This second edition is a great step forward from the first edition. It contains information about genetic tests now in common use. Additional descriptions of test methods with simply illustrated figures have been added to this edition. The authors of the individual chapters have all taken significant steps to make the tables that indicate the diagnostic tests for different clinical conditions more concise and easy to understand. It is now clear that significant morbidity and mortality occur on a daily basis, affecting thousands of patients, because incorrect tests are ordered, important tests for the diagnosis are omitted, and/or the interpretation of test results by the physicians who ordered the tests is incorrect. A survey of medical schools currently underway has shown that the teaching of laboratory medicine over the full 4 years of medical school includes (as a mean value across the US medical schools) only about 10 hours of formal training in laboratory medicine. This study also shows that, unlike virtually every other medical discipline, laboratory medicine is commonly not taught by experts in the field, even if they are present in the institution. As a result, medical schools graduate physicians who have had almost no training in something they do virtually every day—order laboratory tests and interpret the test results. Surprisingly, the patients and the medical institutions suffer cost and care disadvantages quietly and unknowingly. There are surely hundreds of patients every month in the United States who present to an emergency room with shortness of breath, for whom a diagnosis of pulmonary embolism is overlooked, and an appropriate test (the D-dimer test for pulmonary embolism) is not ordered. Such patients are discharged from the emergency room without ever being anticoagulated, and for some, to die shortly thereafter, from an expansion of the pulmonary embolism. Like surgical errors or medication errors, the error of the healthcare provider who did not order a necessary test results in a preventable death—but unlike surgical and medication errors, the fact that such a case represents a preventable death is rarely recognized by the patient, the patient's family, fellow physicians, and often even the physician who failed to order the correct test.

There are several groups of healthcare providers who would benefit significantly by using this book to correctly order laboratory tests and correctly interpret the test results. Certainly, there is every reason to believe that medical students can learn the histopathologic changes associated with a disease using a textbook such as the Robbins Pathologic Basis of Disease, and learn laboratory tests associated with that disorder, using this book, at the same time.

Medical technology students would greatly benefit by a thorough understanding of the methods that are illustrated in Chapter 2 of this book. In addition, it would be of immense benefit for medical technology students to more fully understand the clinical significance of the test results that they generate so that they can more knowledgeably interact with
physicians who are confused about laboratory test results. Interactions between medical technologists and physicians ordering tests that result in improved performance in test selection and result interpretation would greatly increase the respect for the medical technologist (also known as clinical laboratory scientist) from physicians who use the clinical laboratory.

In conversations with primary care physicians attempting to select the correct laboratory tests, they often indicate that one of their first inquiries about which laboratory tests to select is to search Wikipedia. It is most likely that there is a table in this textbook, written by a prominent expert in the field, that will tell a practicing physician exactly what test to order, and importantly, how to interpret the result as well by describing common interpretation mistakes – with a much higher reliability than virtually all of what is available on the Internet.

It is my greatest hope that the use of this textbook, which presents the entire field of laboratory medicine to a large audience of future physicians, medical technologists, and healthcare providers ordering laboratory tests, will result in better clinical outcomes for patients at a greatly reduced cost.

Michael Laposata
Galveston, Texas
Acknowledgments

I would first like to acknowledge all the expert chapter authors associated with this textbook. Many of them have been close professional friends for many years, and I am deeply honored to be a colleague of theirs. I also worked closely with Mr. Robert Pancotti at McGraw-Hill in the production of the first edition of the book, and Ms. Cindy Yoo in production of the second edition. They are both effective editors. I would also like to extend my deepest thanks to the others at McGraw-Hill who have been involved in the production of this book. I am delighted that this book has been included in the Lange series of medical books, which has such a proud tradition in medical education.
samples and serum samples are unacceptable. For other compounds, both plasma samples and serum samples may be acceptable. However, there may be differences, often minor, in the results obtained using plasma versus serum. Potassium is 1 such compound in which reference ranges may be different for plasma and serum. There is a significant movement away from the use of serum in favor of plasma. The principal reason for this is that extra time is required for samples to clot so that serum may be generated. A sample collected into a tube with anticoagulant results in the generation of plasma rather than serum after the tube is centrifuged. The clotting step is omitted when plasma samples are prepared, and therefore the turnaround time for the performance of the test is shortened. In some circumstances, whole blood is used for analysis, but the number of tests performed using whole blood is very limited. Urine and other body fluids, such as pleural fluid and cerebrospinal fluid, are also used for testing. Some of the entries in the table are associated with a fluid other than plasma, serum, or whole blood.

The conventional units in this table are the ones most commonly used in the United States. Outside the United States, SI units are the predominant nomenclature for laboratory test results. The base units in the SI system related to laboratory testing that are found in this table include the mole (amount of substance), meter (length), kilogram (mass), second (time), and Celsius (temperature).

Reference ranges vary depending on the instrument and the reagents used to perform the test. Therefore, the reference ranges shown in this table are only close approximations to the adult reference ranges found in an individual clinical laboratory. It is also important to understand that reference ranges can be significantly affected by age and sex.

Conversion factors are provided in the table to allow the reader to convert conventional units to SI units and vice versa. The conversion of the conventional unit to SI unit requires a multiplication with the conversion factor, and conversion of the SI unit to the conventional unit requires division by the conversion factor.

The sample fluid is sometimes highly restrictive. For example, coagulation tests must be performed using plasma samples and serum samples are unacceptable. For other compounds, both plasma samples and serum samples may be acceptable. However, there may be differences, often minor, in the results obtained using plasma versus serum. Potassium is 1 such compound in which reference ranges may be different for plasma and serum. There is a significant movement away from the use of serum in favor of plasma. The principal reason for this is that extra time is required for samples to clot so that serum may be generated. A sample collected into a tube with anticoagulant results in the generation of plasma rather than serum after the tube is centrifuged. The clotting step is omitted when plasma samples are prepared, and therefore the turnaround time for the performance of the test is shortened. In some circumstances, whole blood is used for analysis, but the number of tests performed using whole blood is very limited. Urine and other body fluids, such as pleural fluid and cerebrospinal fluid, are also used for testing. Some of the entries in the table are associated with a fluid other than plasma, serum, or whole blood.

</table>

The sample type listed under Specimen in this table shows the reference interval for that specimen type. Thus, if the specimen for a test is listed as serum, the reference interval shown is for serum specimens. For many tests listed with serum as the specimen type, plasma is also acceptable, often with a similar reference interval.

$^a$The SI unit katal is the amount of enzyme generating 1 mol of product per second. Although provisionally recommended as the SI unit for enzymatic activity, it has not been universally accepted. It is suitable to maintain use of U/L in these circumstances (conversion factor 1.0).

$^b$For this analyte, there is age dependence for the reference range. There may be several different normal ranges for different pediatric age ranges. Consult your clinical laboratory for the local institution age-specific reference range. Pediatric reference values may also be found in Soldin SJ, Brunnara C, Wong EC, eds; Hicks JIA, editor emeritus. *Pediatric Reference Intervals*. 5th ed. (formerly *Pediatric Reference Ranges*). Washington, DC: AACCP Press; 2005.

LEARNING OBJECTIVES

1. To understand the concepts of sensitivity, specificity, predictive value, prevalence, and incidence.

2. To learn the frequently encountered preanalytical variables that influence laboratory test results.

3. To identify the well-known interferences in many of the laboratory tests.

4. To understand the individual steps in specimen processing and handling.

5. To understand the guidelines for appropriate selection of laboratory tests.

6. To understand how cell injury and inflammation result in the generation of plasma markers of these processes.

CHAPTER OUTLINE

Analytical and Statistical Concepts in Data Analysis 2
- Ranges Used in the Interpretation of Test Results 2
- The Reference Range 2
- The Desirable Range 2
- Therapeutic Range 2
- Interpretations of Clinical Laboratory Test Results that Do Not Involve the Use of a Range 3
- The Need for a Diagnostic Cutoff 3
- The Definition of Sensitivity of a Laboratory Test 4
- The Definition of Specificity of a Laboratory Test 4
- The Identification of the Appropriate Value for the Diagnostic Threshold 4
- The Definition of Predictive Value of a Positive Test 5
- The Definition of Predictive Value of a Negative Test 5
- The Difference Between Prevalence and Incidence 6
- Precision versus Accuracy 6
- Analyzing Errors in Laboratory Performance 6
- Minimizing Errors in the Selection of Laboratory Tests 7
- Minimizing Errors in the Interpretation of Laboratory Test Results 7

Preanalytical Variables that Affect Laboratory Test Results 7
- The Effect of Age on Laboratory Tests 7
- The Effect of Gender on Laboratory Tests 7

A n understanding of the principles set forth in this chapter is essential for the appropriate selection of laboratory tests and the accurate interpretation of the test results.

**ANALYTICAL AND STATISTICAL CONCEPTS IN DATA ANALYSIS**

**Ranges Used in the Interpretation of Test Results**

In clinical practice, the laboratory test result is typically placed alongside a range of values for that test. In most cases, this is the reference range, which is often considered to be the normal range. It is important to understand that individuals with values inside the reference range may have subclinical disease, despite the presence of an apparently normal value. The reference range is dependent on the instrument and reagent used to perform the test. The reference ranges are ideally established inside the laboratory where the test is being performed. Reference ranges supplied by instrument and reagent manufacturers are not likely to correspond perfectly to ranges generated within an individual laboratory. This is because the population used to establish the range by the manufacturer and/or the instruments and reagents used by the manufacturer are likely to be different from those in an individual clinical laboratory.

**The Reference Range**

To obtain a reference range, individuals without disease and on no medications donate samples for testing. A distribution of these values, which should be numerous enough to be statistically reliable, is plotted. The data are not always distributed in a Gaussian pattern. Therefore, statistical methods that are nonparametric are used to identify the central 95% of values. This range, representing the middle 95% of results, is the reference range. As an indication that being outside the reference range does not always reflect the disease, 5% of normal healthy, nonmedicated individuals who donated samples for the reference range determination now fall outside of what has become the reference range for the test.

**The Desirable Range**

Several decades ago, the results for cholesterol testing demonstrated that individuals eating a high-fat diet showed high cholesterol levels that were associated with atherosclerotic vascular disease. When these apparently healthy, nonmedicated individuals provided samples for reference range determinations, the central 95% of values from this population provided an inappropriately high reference range. Therefore, the use of the classical reference range for selected laboratory tests in certain populations was not recommended. For that reason, desirable or prognosis-related ranges were developed. These are commonly established by groups of experts associating laboratory test results with clinical outcome.

**Therapeutic Range**

For certain medications, a therapeutic window exists to provide a target for a blood, plasma, or serum level for the medication. Values below the therapeutic range typically reflect an inadequate amount of medication, and values above the therapeutic range may be associated with a particular toxic effect. In some cases, the therapeutic range does not reflect the amount of medication in the blood, but instead reflects a therapeutic effect produced by the drug. For example, patients taking the drug warfarin are not monitored with warfarin levels in the blood. Instead, the warfarin decreases the level of coagulation factors, which results in a prolonged prothrombin time (PT), and a calculated value known as the international normalized ratio (INR). The therapeutic range of warfarin, therefore, is determined by its effect rather than its concentration in the blood.
For certain laboratory tests, the presence of disease is associated with a value that is above a threshold. The use of troponin as a marker for myocardial infarction involves a threshold value, such that a level above the threshold is consistent with cardiac ischemia. Another prominent example is related to the detection of drugs of abuse. Any level above zero, as a threshold value, provides evidence for the ingestion of an illicit drug.

For laboratory tests that show too much variability to permit the use of a range or a threshold, an individual laboratory result for a specific patient can be compared with a result for that same patient that was generated previously. The longitudinal analysis of results over time can indicate the progression or regression of the disease.

The Need for a Diagnostic Cutoff

Figure 1–1 shows 2 populations of individuals and their results for a particular test. All of the individuals who do not have disease have a low value for the test, and all of the individuals with disease have a high value for the test. There is no overlap between groups in Figure 1–1. In Figure 1–2, a more commonly encountered situation is shown. There is overlap in laboratory values between individuals with disease and those without disease. This means that the diagnostic threshold will necessarily misclassify some patients to create false-positives, false-negatives, or both.

FIGURE 1–1  A clinical situation in which the diagnostic threshold completely separates those with disease from those without disease.

FIGURE 1–2  A clinical situation in which a diagnostic threshold is selected to maximize sensitivity.
The Definition of Sensitivity of a Laboratory Test

The population of individuals who have disease is the focus of sensitivity. The sensitivity of a laboratory test is its capacity to identify all individuals with disease. The threshold used in Figure 1–2 maximizes sensitivity by placing all those with disease above the line. This placement of the diagnostic threshold would decrease the number of false-negatives (those with disease who fall below the line), because everybody with the disease would have a positive test result. However, there is a significant misclassification of individuals without disease. As the diagnostic threshold is lowered, an increasing number of patients without disease would be told they have a positive test result, and by implication, the disease in question. The formula for sensitivity is:

\[ \frac{\text{true-positives}}{\text{true-positives} + \text{false-negatives}} \times 100 \]

True-positives and false-negatives are groups with disease; as noted above, sensitivity focuses on those with disease.

The Definition of Specificity of a Laboratory Test

The population of individuals without disease is the focus of specificity. Specificity is a statistical term that indicates the effectiveness of a test to correctly identify those without disease. When used to describe a laboratory test, it does not refer to its ability to diagnose a “specific” disease among a group of related disorders. One could maximize specificity by raising the threshold shown in Figure 1–3 to place all those without disease below the line. This would decrease the number of false-positives because everyone without disease would have a negative test result. However, there would be a significant misclassification of the individuals with disease. As the diagnostic threshold is raised, an increasing number of patients with disease would be told they have a negative test result and, by implication, no disease. The formula for specificity is:

\[ \frac{\text{true-negatives}}{\text{true-negatives} + \text{false-positives}} \times 100 \]

True-negatives and false-positives are the groups without disease; as noted above, specificity focuses on those without disease.

The Identification of the Appropriate Value for the Diagnostic Threshold

For diseases that are serious and treatable, and for which a second confirmatory laboratory test exists, it is important to maximize sensitivity as in Figure 1–2. For example, for diagnosis of

![FIGURE 1–3 A clinical situation in which a diagnostic threshold is selected to maximize specificity.](image)
AIDS, it is better to have a few false-positives that can be subsequently correctly identified with a confirmatory test than to fail to identify individuals with HIV infection who might unknowingly infect others. However, for diseases that are serious and not curable, a false-positive result is catastrophic for the patient. For such diseases, such as pancreatic cancer, it is better to use the threshold shown in Figure 1–3 for diagnosis because if individuals with disease are missed, it will have no effect on the treatment or outcome. When there are no compelling reasons to maximize either sensitivity or specificity, the threshold value should be established to minimize the total number of false-positives and false-negatives, as shown in Figure 1–4.

The Definition of Predictive Value of a Positive Test

The population of individuals with a positive test result is the focus of positive predictive value. The positive predictive value for a laboratory test indicates the likelihood that a positive test result identifies someone with disease. It should be noted that the predictive value of a positive test is greatly influenced by the prevalence of the disease in the area where testing is performed. As an example, a screening test for HIV infection is more likely to be confirmed as positive in an area where many individuals are infected with HIV, as opposed to a location where there is only a rare case of HIV infection. In the latter situation, most of the positive HIV tests in the initial evaluation of a patient are found to be false-positives by confirmatory tests. A high percentage of false-positives from a low prevalence disease, as shown in the following formula, decreases the predictive value of the positive test:

\[
\text{true-positives} \div \text{true-positives + false-positives} \times 100
\]

True-positives and false-positives are the groups with a positive test result; as noted above, positive predictive value focuses on those with a positive test.

The Definition of Predictive Value of a Negative Test

The population of individuals with a negative test result is the focus of the negative predictive value. The negative predictive value for a laboratory test indicates the likelihood that a negative test result identifies someone without disease. It is not greatly influenced by the prevalence of disease because false-positives are not included in the formula for negative predictive value. The formula for predictive value of a negative test result is:

\[
\text{true-negatives} \div \text{true-negatives + false-negatives} \times 100
\]

True-negatives and false-negatives are the groups with a negative test result; as noted above, negative predictive value focuses on those with a negative test result.
CHAPTER 1  Concepts in Laboratory Medicine

The Difference Between Prevalence and Incidence

The prevalence of a disease reflects the number of existing cases in a population. It is usually expressed as a percentage of a certain population. Incidence refers to the number of new cases occurring within a period of time, usually 1 year. For example, in the United States, sore throat has a low prevalence because considering the size of the population there is a low percentage of individuals at a given time afflicted with sore throat. However, it has a high incidence because many new cases of sore throat appear each year.

Precision versus Accuracy

Precision refers to the ability to test 1 sample and repeatedly obtain results that are close to each other. This does not infer that the mean of these very similar numbers is the correct number (see Figure 1–5). Some analyses, which have great precision, are very inaccurate. The accuracy reflects the relationship between the number obtained and the true result. Thus, a sample could have high accuracy but low precision if it provides the correct answer but has substantial variability as the sample is repeatedly tested.

Analyzing Errors in Laboratory Performance

There are 3 phases of laboratory analysis. The first of these is the preanalytical phase. This time frame is from patient preparation for the laboratory test, through the time of sample collection, until the sample arrives in the laboratory. Most of the errors in laboratory test performance occur in this phase. Examples of preanalytical errors are: inappropriate preparation of the patient, such as not fasting for a particular test in which fasting is required; ingesting drugs that will interfere with the laboratory tests; collection of the specimen in the wrong tube; delayed transport of the specimen to the laboratory; storage of the sample at an incorrect temperature; and collection of an inadequate amount of blood in vacuum tubes containing a fixed amount of anticoagulants. All these errors occur before the sample arrives for analysis and make it impossible, no matter how great the analytical precision within the laboratory, to provide a test result that truly reflects the patient’s condition. The second phase is the analytical phase, which is the time that the sample is being analyzed in the laboratory. Errors can occur during this process, but they are much less common now because of the high level of automation of many laboratory instruments. Examples

---

**Figure 1–5** A series of “bulls-eye” illustrations that display excellent or poor precision and accuracy.
of analytical errors are: incorrect use of the instrumentation and the use of expired reagents. The third phase of laboratory test performance is the postanalytical phase, which begins when the result is generated and ends when the result is reported to the physician. Example of errors in this phase, which are more common than analytical errors but less common than preanalytical errors, are: delay in time to enter a completed result into the laboratory information system and reporting results for the wrong patient.

Minimizing Errors in the Selection of Laboratory Tests

As the number of laboratory tests has increased in size, complexity, and cost, health care providers are highly challenged to select the correct tests, and only the correct tests, in pursuit of a diagnosis. One approach commonly implemented to assist physicians in correct test selection is the use of a reflex test algorithm. Tests are ordered by algorithm selection, such as selection of an algorithm to determine the cause of a prolonged PTT result. Using the algorithm, the clinical laboratory notes the results of the first test in the algorithm, and that result determines which test is performed next. For example, if the prolonged PTT is further evaluated with a PTT mixing study, a normal result would direct testing toward assays for factors VIII, IX, XI, and XII. An elevated result in the PTT mixing study, on the other hand, would direct testing toward an inhibitor in the PTT reaction, such as a lupus anticoagulant. Testing is continued within the algorithm until a diagnosis, which explains the prolonged PTT in this case, is identified.

Laboratory test selection is also made more difficult because many laboratory tests have synonyms, and many compounds have related forms. For example, the test most commonly known as the lupus anticoagulant is also called the lupus inhibitor, and the general term that includes the lupus anticoagulant and related entities is antiphospholipid antibody. Vitamin D has several isoforms that include 25-hydroxyvitamin D and 1,25-dihydroxyvitamin D. Incorrect laboratory test selection is a major source of medical error.

Minimizing Errors in the Interpretation of Laboratory Test Results

With thousands of tests on the clinical laboratory test menu, it is impossible for a health care provider to understand the clinical significance of an abnormality for each test. This has become particularly noteworthy with the introduction of tests for genetic alterations, because there are so many and the clinical significance of the alterations may not yet be well established. In some institutions, narrative interpretations of complex clinical laboratory evaluations are prepared by experts in the field. In most institutions, such narratives require a special request for completion, but an emerging concept is to provide narrative interpretations for all complex clinical laboratory evaluations automatically, as they are provided in radiology and in anatomic pathology. Misinterpretation of laboratory test results has been increasingly noted as a source of poor patient outcome.

PREANALYTICAL VARIABLES THAT AFFECT LABORATORY TEST RESULTS

The Effect of Age on Laboratory Tests

There are a number of laboratory tests that have different normal ranges for patients of different ages. This is particularly important in pediatrics. Newborns especially have many different normal ranges than adults or older children for substances in blood and other bodily fluids. For example, several of the coagulation factors do not reach adult levels for many months after birth. As a second well-known example, the cholesterol level rises with age.

The Effect of Gender on Laboratory Tests

Gender has a significant bearing on many laboratory tests. Testosterone and estradiol are obvious examples. In addition, among women there are variations in the serum concentration of various hormones throughout the menstrual cycle.
The Effect of Body Mass on Laboratory Tests

Muscle mass can affect the level of certain compounds, such as creatine kinase, in the blood. It is also known that there is an increase in the serum cholesterol level with obesity, because the cholesterol level is related to the amount of body fat.

Preparation of the Patient for Laboratory Testing

For certain laboratory tests, there are a number of special preparations of the patient that are necessary to provide the most clinically useful, accurate, and precise result. One of the most commonly encountered patient preparations is fasting, usually for 8 to 12 hours, depending on the test. The serum triglyceride level can be significantly affected by eating, and fasting is absolutely required. Another test for which fasting is required is the fasting blood glucose used in the evaluation of a patient for diabetes.

Patient Posture for Blood Collection

Patient posture may affect the result for certain tests. There is a lower plasma volume when the patient is upright because there is pooling of fluid in the dependent parts of the body when standing. When the patient is supine, there is a movement of fluid back into the circulation from the tissues. The extra volume in the circulation can dilute certain compounds in the blood. It is best to monitor the patient in the same postural position if the test result is affected by posture and if the values need to be compared with one another over time.

Differences in Test Results Between Samples of Venous, Arterial, and Capillary Blood

Venous blood may have a different concentration of a compound than arterial blood. The best examples are the blood gases that show marked differences between arterial and venous blood because of the exchange of gases in the lungs. There may also be a difference between capillary blood and arterial and venous blood. Blood glucose values may differ significantly in capillary (finger-stick) samples from venous or arterial blood.

INTERFERENCES IN LABORATORY TESTS

Analytical Interferences in Laboratory Testing

Interferences may result in falsely high or falsely low values, depending on the interfering substance and the particular test. Although there are many compounds that can interfere with the accurate and precise quantitation of a compound, there are 3 major interferences that must be considered when selecting and interpreting results of laboratory tests. These are hemolysis that makes plasma and serum red; elevated bilirubin that makes plasma and serum shades of orange, green, or brown; and lipemia that makes plasma and serum milky white. There are many drugs, particularly those that color the plasma and serum, that can produce significant analytical interference. Many automated laboratory tests are spectrophotometric, and therefore depend on measurable changes in the color of plasma or serum after a chemical reaction. This is why alterations in the color of the serum or plasma often interfere with laboratory test performance.

Impact of Drugs on Laboratory Test Results

Drugs can affect laboratory tests in 2 ways—as an interfering substance in the laboratory test only and by producing an effect in the body that alters a laboratory test result. For example, there are many drugs that will increase the PT in patients receiving warfarin (coumadin) by an in vivo potentiation or diminution of warfarin-induced anticoagulation. There are a number of drug effects, however, that alter the result of a particular test strictly in vitro, and do not change anything in vivo.
TEST SELECTION GUIDELINES

The Use of Screening Tests Before Esoteric Tests
Screening laboratory tests are typically inexpensive, easy-to-perform assays that indicate whether additional tests need to be performed to reach a diagnosis. Whenever possible, if a screening test is available, it should be used before the more expensive or time-consuming tests are performed. An example of the use of a screening test is the partial thromboplastin time (result within minutes/hours and at low cost) to assess a major portion of the coagulation cascade. Only if this value is elevated should tests be performed for PTT-related coagulation factor deficiencies (results within several hours and at high cost).

The Danger of Ordering Too Many Laboratory Tests
As noted in the discussion of the normal range, 5% of individuals who have no disease can fall outside of the reference range established by the central 95% of healthy individuals. Thus, if an individual without disease has 20 different tests, it is likely on a statistical basis that he/she will have 1 abnormal value (5% = 1 of 20). In medical practice, the abnormal test result for the normal patient often leads to further evaluation and raises suspicion for a disease that does not exist. Thus, by limiting the number of tests ordered for a patient to those relevant to the clinical presentation of the patient, one is less likely to encounter false-positive or false-negative results.

SPECIMEN PROCESSING AND HANDLING

The Importance of Turnaround Time
An accurate and precise laboratory test result provided after a decision has been made regarding patient management is of no value. Since results for all laboratory tests cannot be provided immediately, the physicians and laboratory personnel must decide on clinically relevant turnaround times for each laboratory test. In addition, if a patient is not discharged from the hospital because of a delay in laboratory testing, this may have a significant financial impact from unnecessary length of stay. All steps related to turnaround time, from ordering of the test to the reporting of the result, must be carefully analyzed and shortened as much as possible.

Tubes for Blood Collection
There are a number of different tubes into which blood may be collected. The tubes used for the vast majority of collections contain a vacuum to help draw the blood into the tube. The tops of the tubes have a different color depending on the contents of the tube prior to blood collection (Table 1–1). Several of the tubes contain anticoagulants to prevent the clotting of the blood in the tube. Clotted blood that is centrifuged to remove the clot and any cells is known as serum. Blood that has not been clotted and is then centrifuged to remove any cells is known as plasma. For many laboratory tests, the same result is obtained in an assay if serum or plasma is used. However, this is often not the case. The clotting of the blood, for example, makes blood cell counts and coagulation tests impossible because the clotting factors are consumed in the clot and the blood cells become trapped in it. If the clotting of the blood to form serum is not absolutely necessary, tests can be performed with a shorter turnaround time using plasma because there is no requisite time to wait for the blood clot to form. The amount of anticoagulant in the light blue-top tube must be in a specific proportion to the blood volume in the tube, usually 9 parts blood to 1 part citrate solution. When an inadequate amount of blood is collected into a blue-top tube, the ratio of blood to anticoagulant is less than 9:1. This can result in spuriously high values for the PT and PTT tests. Thus, light blue-top tubes must be filled appropriately to obtain accurate results for clotting tests.

Timing of Blood Collection
Patients may have a need to present for phlebotomy at a certain time of the day if the parameter being measured has a diurnal variation in its concentration.
Dynamic tests involve the measurement of a patient response to a treatment or stimulus, and timing of collection is important in these studies. The oral glucose tolerance test, in which plasma glucose levels are measured after the oral ingestion of a glucose solution, is an example of such a test.

A third situation in which timing of sample collection is important is in therapeutic drug monitoring. The serum level of certain drugs is measured to determine if the concentration is within the therapeutic window. The serum level of a drug varies greatly as the drug is absorbed, distributed, and metabolized, so the timing of collection must be consistent. For the monitoring of many drugs, a “trough” level is obtained just before the next dose of the drug is administered.

**EFFECTS OF CELL INJURY AND INFLAMMATION ON SELECTED LABORATORY TESTS**

**The Release of Plasma Markers of Organ Damage from Injured Cells**

When cells are injured, components of the cells can leak out of the damaged or dead cells and make their way into the systemic circulation. This permits the measurement of these “marker” compounds in the serum or plasma as a test for injury to the organ. The most important features of plasma markers of cell injury are that: 1) they are not rapidly removed from the circulation; 2) they are relatively organ specific so that the damaged organ is identified; and 3) the compound is precisely and accurately measured in the clinical laboratory. A well-known example includes the release of the creatine kinase-MB fraction and troponin from myocardial cells injured by ischemia in myocardial infarction.

**Markers of Inflammation and the Acute-phase Response**

The concentration of many plasma proteins changes significantly in patients with inflammation. Infections (even minor viral illnesses), autoimmune disorders, and many other conditions result in an increased concentration of proteins known as acute-phase reactants. Commonly used tests to assess the severity of inflammation, from whatever cause, are the erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP). Examples of acute-phase reactant proteins include fibrinogen, which can rise as much as 10-fold over baseline, and von Willebrand factor, which can rise 2- to 3-fold over baseline. The rise in von Willebrand factor with inflammation can mask a deficiency of von Willebrand factor in patients with von Willebrand disease, and this highlights the need to obtain baseline values after an acute-phase response subsides for accurate diagnosis.
The Serologic Diagnosis of Infectious Disease

It is not uncommon to suffer an infection with an organism that is not identifiable by Gram staining or other microscopic analysis and is not readily cultured. For these infections, the diagnosis is often made by identifying and measuring the amount of antibody produced in response to an antigen derived from the infectious agent. The antibody response typically takes several days to a week or 2 (dependent on past exposure) to emerge, and the appearance of IgM antibody before IgG occurs in most infections. This is why the presence of IgM antibody in a serologic test is likely to reflect an acute infection rather than past exposure. Serologic tests may also be designed to detect and measure an antigen associated with the infectious agent. This obviates the inherent delay in diagnosis of the infection of up to approximately 2 weeks while waiting for the antibody response to occur.

No textbook in laboratory medicine would be complete without a description of methods used in the clinical laboratory. The methods described in this chapter are predominantly the common ones found in clinical laboratories. Each method description provides an overview of the basic concept of the assay, minimizing the details, while including clinically important information and a comment on the expense of the test and the complexity of the assay in the laboratory.
Some methods describe specific assays used almost exclusively in the clinical laboratory. For example, the PT and PTT are tests used for clinical assessment, with the goal to identify factor deficiencies in the coagulation cascade. Other methods are standard techniques used inside and outside the clinical laboratory. As an example, flow cytometry is a standard technique used in a variety of settings, and in this chapter it is shown how it is used in clinical laboratory testing.

There is rapid growth of testing in the clinical laboratory for genetic alterations. These laboratory studies are often highly complex and very expensive, and it is difficult for most clinical laboratories to perform them for these reasons. In addition, the clinical impact of many genetic alterations remains unknown. Therefore, it is not uncommon for a genetic test, especially an assay involving gene sequencing, to produce results that have no known clinical significance. Several genetic methods are illustrated in this chapter.

Some tests are performed outside the laboratory in the vicinity of the patient. These tests are called "point-of-care tests," commonly abbreviated as POCT. This section contains illustrations for point-of-care testing for glucose and for point-of-care testing for a variety of compounds that can be detected by immunological methods (immunoassays).

The expense assessment attached to each assay described in this chapter is an approximation, listed as low, moderate, or high. It should be understood that the charge for the test set by the institution operating the laboratory is usually proportional to the expense of the reagents, supplies, and labor required to perform the test. On occasion, however, there is a great disparity between the actual expense to perform the test and the amount charged by the institution for the assay. With this in mind, the expense estimation provided for each method in this chapter is more closely related to the actual cost of reagents, supplies, and labor in the laboratory, with the understanding that the amount charged for the test should be in the same range of low, moderate, or high—but it is not always the case.

Each method also has a descriptor to reflect whether it is manual, semiautomated, or highly automated. A comment has been added if microscopy is involved, as this makes any technique highly manual. It should be noted that for some methods, there is an option for manual performance or for using some level of automation. Manual methods are often less expensive. There is usually greater automation in the larger clinical laboratories because larger laboratories are more likely to have the test volume and the financial resources to justify the automated option. The term semiautomated indicates that there is a manual component associated with the use of an instrument that performs some steps of the analysis.

The turnaround time for an assay is not provided because it is impossible to know all of the elements associated with the turnaround time for a test within an individual institution. Broadly speaking, the turnaround time is shorter for assays that are highly automated and less expensive, and longer for assays that are manual and highly expensive. It is important to understand that the turnaround time for an assay can be calculated using different starting points. For example, 1 starting point is the time a sample is collected. Another starting point is the time that a sample enters the laboratory. However, the most relevant starting time clinically, which predates the previous 2 starting times, is the time at which the physician orders the test. Similarly, there are different end points in the assessment of turnaround time. Most commonly, the end point is the time at which the result is reported by the laboratory into the laboratory information system. However, it is most important to know when the physician becomes aware of the result. This end point is extremely difficult to ascertain, and, therefore, virtually always the end point is considered to be the time at which the result is reported by the laboratory.

Finally, it should be noted what methods are not presented in this chapter. There are a number of methods that have been used progressively less over time, and in many institutions these assays are no longer performed at all in the clinical laboratory. These are numerous and include the radioimmunoassay (RIA), immunoelectrophoresis, lipoprotein electrophoresis, and the bleeding time. Also less frequently performed assays are not described in this chapter. Though this number of methods may be large, the number of tests performed using these methods account for a small percentage of the total tests performed in a typical hospital clinical laboratory.
Antinuclear antibody (ANA) testing

Expense: Low

Manual with microscopic evaluation

If an antibody is detected, the patient’s serum is progressively diluted until the staining is no longer detected. The final result includes the highest serum dilution producing a detectable response and the pattern of nuclear staining.

Cells on glass slides incubated with patient serum—with or without antinuclear antibodies

If antibodies are present, they bind to nucleus

Antinuclear antibody in patient serum

Antibody binding is detected by adding fluorescent labeled anti-IgG antibodies

Fluorescent staining of nucleus can be homogeneous over the nucleus, stain the rim of the nucleus, stain the nucleoli, or produce a speckled stain of the nucleus.

Fluorescent labeled antibody reveals patient’s antinuclear antibody

FIGURE 2–1
Protein electrophoresis (PEP)

**Expense: Moderate**

Sample can be:
- Serum for SPEP analysis
- Urine for UPEP analysis
- Cerebrospinal fluid (CSF)

Urine and CSF are usually concentrated prior to testing to increase the concentration of proteins in sample

A sample with an additional monoclonal protein, which can appear in multiple myeloma, for example, shows a dense band of protein not present in a sample from a healthy individual

**Semiautomated**

During electrophoresis, proteins migrate within gel to different locations

**Area of gel:**

- Beta 2
- Alpha 2
- Beta 1
- Alpha 1
- Gamma
- Other proteins
- Albumin

Prominent albumin band

Bands of proteins are generated by electrophoresis and made visible by staining the gel

Normal serum

Serum from patient

Monoclonal protein

FIGURE 2–2
Immunofixation to identify monoclonal immunoglobulins

**Expense: Moderate**

Patient specimen is serum or urine most often, and occasionally cerebrospinal fluid (CSF)

**Semiautomated**

Multiple aliquots of same sample onto an agarose gel

Proteins separated in gel in individual lanes

Antibodies soaked into strips are overlaid onto each lane

This patient has an IgA λ monoclonal immunoglobulin

Flow cytometry for identification of cell type and assessment for cell surface markers

Expense: High

For identification of cell type
- Much manual processing with moderately complex instrumentation

For assessment of cell surface markers
- Cell suspension mixed with antibodies to different cell surface markers — each of which has a unique fluorescent label (F1 is different from F2)

As cells flow in a stream within the instrument and are exposed to laser light, each fluorescent compound can be identified — fluorescent cells are positive for the cell surface marker with the specific fluorescent antibody to that surface marker.

FIGURE 2–4
Nephelometry for quantitation of selected proteins and other compounds

Expense: Moderate

Sample of any body fluid is incubated with an antibody to the compound being measured

When the compound is present, antigen–antibody complexes form

Antibody to the compound is the reagent added to the sample

Antigen is compound being measured

The amount of scattered light is proportional to the amount of compound being measured

Antigen–antibody complexes scatter light from a beam of light shown through the sample

FIGURE 2–5
Cryoglobulin analysis

Expenses: Moderate

Highly manual method

Cryoglobulins are proteins which precipitate out of serum at a temperature < 37°C

Therefore, all specimen transport and processing steps must be performed at 37°C or the cryoglobulin may precipitate out of serum unintentionally prior to analysis.

Patient serum at 37°C

Sample split into 2 separate tubes and both placed at 4° for 1–3 days

Cryoglobulin in this tube processed by electrophoresis

Tube used to measure a packed “cryocrit” at 72 hours

Monoclonal immunoglobulins only

Cryoglobulinemia type I

Mixed monoclonal and polyclonal immunoglobulins

Cryoglobulinemia type II

Polyclonal immunoglobulins only

Cryoglobulinemia type III

FIGURE 2–6
**Gram stain**

**Expense: Low**

- Patient specimen is any sample that can be applied to a glass slide

**Manual with microscopic analysis required**

- The material on the glass slide from the patient is dried and fixed

- The slide is ultimately subjected to 2 stains

  - Gram positive organisms stain purple
  - Gram negative organisms are red
  - Nonbacterial cells, such as white blood cells, show staining characteristics of the cell type

- The color, shape, and arrangement of bacteria are described in the microscopic analysis

  - “Gram positive cocci in clusters” is one possible observation in review of a gram stain

- Purple, circular bacteria in clusters, not chains, are shown here

**FIGURE 2–7**
## Microbiologic culture and organism identification

**Expense:** Moderate to high, depending on the extent of the evaluation

**Mostly manual with much visual inspection of colonies in different culture media**

<table>

</tr>
</tbody>
</table>

| Isolation of organisms | Colonies growing on agar surfaces are first characterized by colony morphology which provides an early clue to organism identification—and then colonies of interest can be subcultured for species identification |

| Identification of organisms | Microorganisms originating from an isolated colony can be tested in a panel of biochemical tests—the results of which identify the microorganism with a percent likelihood |

**FIGURE 2–8**
Blood cultures

Expense: High

In most laboratories it is now highly automated

Sample collection

The surface of the arm overlying the venipuncture site must be meticulously cleaned with agents that eliminate skin microorganisms before venipuncture—if not, non-pathogenic skin bacteria can contaminate the blood culture.

Blood with or without microorganisms is collected into bottles for growth in aerobic or anaerobic environments.

Growth of organisms

Bottles are placed into specially equipped incubator for detection of carbon dioxide generated within individual blood culture bottles.

Positive blood culture—
with growth of microorganisms generating CO₂

Sample from positive blood culture bottle is then processed for organism isolation, identification, and antimicrobial sensitivity.

CO₂ detected

FIGURE 2–9
Antimicrobial sensitivity tests

Expense: High

Can be highly manual, as in disc diffusion method, or semiautomated, as in dilution method

Microorganisms originating from an isolated colony are placed in a liquid suspension

Dilution method

Organisms into multiple tubes

More antimicrobial agent into each sequential tube

After incubation, concentration of antimicrobial agent that inhibits organism growth is determined

Minimum inhibitory drug concentration

Organisms growing Organisms not growing

Disc diffusion method

Organisms spread to completely cover a large agar plate which supports organism growth

Discs with different antimicrobial agents placed onto agar surface and drug slowly diffuses from disc

After incubation, agents which inhibit growth of organisms are identified because bacterial growth is far from the disc

Organism-free zone

Drug A Drug B

Drug A is a better antimicrobial agent than drug B

FIGURE 2–10
Direct and indirect immunofluorescence for antigen detection

Expense: Moderate

Direct immunofluorescence

Fluorescent labeled antibody binds to antigen of interest on a glass slide or other surface

Indirect immunofluorescence

Antibody which is not fluorescent-labeled binds to antigen of interest on a glass slide or other surface

Slides read using a fluorescent microscope

Fluorescent labeled antibody to IgG is added and binds to antibody previously bound to antigen

FIGURE 2-11
**Counting of blood cells with automated white blood cell differential count**

**Expense: Low**

- Purple
- Dry EDTA crystals in tube

**Highly automated**

- Whole blood containing RBC, WBC, and platelets in purple top tube containing EDTA

**Diagram Description**

- Cells flow in a column toward tubes with apertures through which blood cells pass and are counted

- Cells passing through smallest aperture are platelets

- RBC not lysed:
  - All but a small percentage of cells passing through large aperture are RBC, which are also sized as they pass through the aperture to determine mean corpuscular volume (MCV)

- RBC lysed:
  - Hemoglobin measured from lysed RBC
  - Cells passing through large aperture are WBC—with flow cytometry in the circuit to identify WBC types by size and granularity

**Hematocrit or packed RBC volume** is calculated from number and size of RBC

**FIGURE 2–12**
Expense: Low

Sample collected into a purple top tube containing EDTA

Smear preparation automated or manual, followed by microscopic examination

Drop of blood is applied to a glass slide and smeared to spread blood cells across slide

Microscopic examination is performed to detect abnormalities in number or in appearance of:

- Red blood cells
- White blood cells
- Platelets

The peripheral blood smear is commonly used early in the diagnostic process to assess a patient for an abnormality involving circulating blood cells

FIGURE 2–13
Sickle cell screening assay

Expense: Moderate

Manual assays, and the sickling test requires microscopic examination

Sample of blood collected into purple top tube containing EDTA—two available tests to detect sickle hemoglobin illustrated here

Sickling test—Blood onto glass slide, followed by addition of reducing agent over blood droplet

Hemoglobin S detected by presence of holly leaf or sickle cells upon microscopic exam

Solubility test—Blood added to a concentrated phosphate buffer solution, followed by RBC lytic agent and reducing agent

Hemoglobin S detected if buffer becomes turbid because hemoglobin S is not soluble in this buffer

Tests are positive for patients with:
Hemoglobin SS (sickle cell anemia)
Hemoglobin AS (sickle trait)
Hemoglobin S with another abnormal hemoglobin (example: hemoglobin SC)

RBC with normal morphology

RBC with abnormal morphology after addition of reducing agent

Cannot see through the specimen to visualize black lines on card behind tube if hemoglobin S is present

FIGURE 2–14
Hemoglobin electrophoresis

Goal of the test is to identify the hemoglobin types present in a patient’s red blood cells (RBC)

Blood collected into a purple—top tube containing EDTA anticoagulant

RBC isolated by centrifugation and washing

RBC lysed and hemoglobin released from cells

Migration of hemoglobins in patient RBC compared to migration of standard hemoglobins (A, F, S, C) on gel

Gel is stained to reveal bands of hemoglobin

Hemoglobins separated by electrophoresis using 1 or more electrophoretic systems

This patient has hemoglobins S and C or hemoglobin SC

Standard hemoglobins

Origin

There are many hemoglobin variants and some overlap with the types used as standards

Hemoglobin types can also be separated by isoelectric focusing and by high performance liquid chromatography (HPLC)

FIGURE 2–15
Erythrocyte sedimentation rate

Expense: Low

Goal of the test is to measure the height of sedimented RBC after an incubation, often 1 hour

Whole blood placed in a cylindrical vessel with markings to assess column height

RBC allowed to sediment undisturbed within cylindrical vessel

Distance sedimented in mm/hr is erythrocyte sedimentation rate

Plasma layer

RBC Layer
The PT and PTT assays

Expense: Low

Highly automated

Blood collected into tube—9 parts of blood per 1 part of citrate (4.5 ml blood into 0.5 ml citrate usually)

Tube centrifuged and plasma removed for testing

For PTT:
Add activator, partial thromboplastin and calcium

For PT:
Add thromboplastin and calcium

Time to clot determined in seconds

FIGURE 2–17
The goal of the test is to determine if a prolonged PT or prolonged PTT is a result of \( \geq 1 \) factor deficiencies or an inhibitor of the PT or PTT clotting reaction.

Most likely an inhibitor to factor VIII

Most likely a factor deficiency

Most likely a lupus anticoagulant for a PTT prolongation, or a rare factor inhibitor other than a factor VIII inhibitor

Most likely an inhibitor to factor VIII

Expense: Low

After samples are mixed, the testing is highly automated

Patient plasma mixed with normal plasma pooled (NPP) from multiple donors in equal amounts

The PT or PTT, whichever is prolonged, is performed with the mixed sample immediately after mixing and up to 1 hr after mixing

Possible results

The prolonged PT or PTT in the patient plasma becomes normal when mixed with NPP—at all time points after mixing

A prolonged PT or PTT in the patient plasma remains prolonged when mixed with NPP—at all time points after mixing

A prolonged PTT (not PT) in the patient plasma shortens toward normal immediately after mixing; when the mixed plasma is tested 30–60 minutes after mixing, the PTT is prolonged

FIGURE 2–18
Coagulation factor assays

Expense: Moderate, due to reagents used

Highly automated after dilution and mixing steps

Patient plasma mixed with plasma totally deficient in the factor being measured

All of the factor being measured is derived from the patient in the mixed plasma

Factor level is determined using a standard curve that relates clotting time to amount of factor

Factor I is fibrinogen and is measured in a separate assay involving thrombin addition to patient plasma and measuring time to clot formation

Factor III is tissue factor and is not measured for clinical assessment

Factor XIII which stabilizes a formed clot can be assessed by several different methodologies

Factors II, V, VII, X measured in a PT-based assay with thromboplastin and calcium

Factors VIII, IX, XI, XII measured in a PTT-based assay with clotting activator, partial thromboplastin and calcium
von Willebrand factor assays

Expense: High

Test for ristocetin cofactor is largely manual, and tests for von Willebrand factor antigen can be semiautomated

Test for von Willebrand factor function: The ristocetin cofactor assay

The amount of von Willebrand factor activity is proportional to the rate at which fixed platelets aggregate in response to ristocetin

Test to assess the amount of von Willebrand factor protein: the von Willebrand antigen assay

Enzyme-linked immunoassay (ELISA) and other methods involving antibody to von Willebrand factor can be used to quantify amount of von Willebrand factor protein

Shallow slope indicates slow aggregation

Steep slope indicates rapid aggregation

High von Willebrand factor activity

Low von Willebrand factor activity

FIGURE 2–20
Platelet aggregation

Expense: High

Manual test requiring careful performance to generate accurate result

Goal of the test is to assess the function of circulating platelets

Sample collected in a blue top tube containing citrate

The sample is centrifuged relatively slowly to sediment the larger and more dense white blood cells and red blood cells from the platelets

Platelet activators added to tubes with platelets—functional platelets will clump and fall to bottom of tube—poorly functioning platelets do not

Platelets remain in plasma

WBC and RBC

Free floating platelets

Platelet rich plasma (PRP) is removed to separate tubes

Result expressed as percent of full aggregation response, as measured spectrophotometrically in a platelet aggregometer

FIGURE 2–21
ABO/Rh typing

Expense: Low

**Forward typing:**
To detect antigens on RBC

Add antibodies to A, B, and Rh antigens in 3 separate tubes (1 for A, 1 for B, 1 for Rh) containing patient RBC

Clumping of RBC indicates presence of antigen on RBC

Failure to clump indicates absence of antigen on RBC

**Reverse typing:**
To detect antibodies in serum which can bind to RBC antigens

Add patient serum with or without anti-A and anti-B antibodies to A positive and to B positive RBC (A cells in 1 tube and B cells in another)

Clumping of RBC indicates presence of antibody to RBC antigen on cells used (either A or B)

Failure to clump indicates absence of antibody to RBC antigen

FIGURE 2–22
Blood component preparation

Expense: Blood products are expensive; separation of whole blood into blood components is moderately expensive

The process of component preparation is manual

Anticoagulated whole blood is obtained from a volunteer blood donor

The bag of whole blood is centrifuged

Packed RBC are obtained and stored at 1–6 °C

Plasma containing platelets is obtained

The bag of platelet rich plasma is centrifuged

Plasma is obtained and stored at <18 °C

Platelet concentrate is obtained and stored at 20–24 °C

If not maintained as fresh frozen plasma, by various methods plasma can be used to prepare cryoprecipitate, immunoglobulins, albumin, or factor concentrates

FIGURE 2–23
The goal of the test is to determine if anything in the blood of a patient recipient will hemolyze or agglutinate the RBC from a potential donor.

Patient serum mixed with RBC from a potential donor, followed by centrifugation, incubation, and addition of other reagents.

Sample checked for hemolysis or agglutination—either of which makes the potential donor blood incompatible for the patient.

Positive for hemolysis or agglutination— incompatible unit—do not transfuse.

Negative for hemolysis or agglutination—compatible unit suitable for transfusion.

Intact RBC with no agglutination.

FIGURE 2–24
Direct antiglobulin test (DAT)

**Expense:** Moderate  
**Largely manual method**

Goal of the test is to determine if IgG immunoglobulin or C3d complement is bound to the surface of the patient’s red blood cells.

Suspension of patient’s RBC placed in 3 separate tubes.

- **RBC + anti-IgG and anti-C3d** (initial test—detects IgG and C3d)
- **RBC + anti-IgG** (performed if initial test is positive)
- **RBC + anti-C3d** (performed if initial test is positive)

If IgG or C3d is present on RBC, antibody binds to RBC, resulting in RBC agglutination and/or RBC hemolysis.

**FIGURE 2–25**
Indirect antiglobulin test (IAT)

Expense: Moderate  Largely manual method

Goal of the test is to detect antibodies *not* bound to RBC present in the plasma or serum of a patient or donor that *can become* bound to RBC

Plasma or serum sample being tested for antibodies to RBC is placed in multiple tubes

To each tube of test sample is added different RBC, and each RBC sample is positive for certain antigens from the Rh, MNS, P, LEWIS, KELL, KIDD, and DUFFY systems

Tube without RBC agglutination or hemolysis

The sample tested does not contain an antibody to the RBC and its associated antigens in this tube

Tube with RBC agglutination (or hemolysis)

The sample tested contains an antibody to an RBC antigen in this tube

Additional testing ultimately reveals the exact RBC antigen to which the antibody in the test sample binds
Apheresis

Collection could be for:
- Plasma (plasmapheresis)
- Platelets (plateletpheresis)
- WBC (leukapheresis)
- RBC (red blood cell exchange)

Goal of the procedure is to selectively remove from the patient’s circulation either plasma, platelets, white blood cells or red blood cells—replacement of plasma or red blood cells can occur depending upon the clinical indication for the procedure.

FIGURE 2–27
Western blot

**Expense: High**

Goal is to identify antibodies in patient serum directed at specific proteins

**Manual method**

Example: Identification of antibodies in serum to proteins within the human immunodeficiency virus (HIV)

Proteins bound to solid phase—but not stained—no protein bands visible

If antibody is present which binds to this protein, it will bind

Antibodies from patient serum

Band of protein

Antibody binding detected by anti-human immunoglobulin linked to an enzyme ⭐

Uncolored substrate

Colored product

Protein band with bound antibody becomes visible

FIGURE 2–28
Electrolyte measurements: Sodium–Na, Potassium–K, Chloride–Cl

**Expense: Low**

Sample can be plasma or serum—since plasma must be clotted to produce serum, and this increases the time to complete the test, plasma has become the preferred specimen.

**Highly automated**

The sample must be carefully collected, handled, and transported to avoid hemolysis—which produces a spuriously high value for potassium.

Detection of individual ions by ion selective electrodes Ionized (free) calcium, among other ions, can also be measured with ion selective electrodes.

**FIGURE 2–29**

Whole blood in anticoagulant heparin in the tube

Whole blood in red top tube without anticoagulant

Incubation to permit clot formation

Plasma

Blood cells

Centrifugation

Plasma can be removed for analysis

Or

Serum specimen removed from clot and blood cells

Plasma specimen for analysis

Be made to clot to produce serum

Blood cells with clot

Centrifugation
**Assays measuring concentration by spectrophotometry**

**Expense: Low**

Highly automated assays for most substances or activities measured

Sample is usually patient plasma or serum—for many assays, either can be used and for others, one or the other is specifically required

**Common scenarios for testing and detection:**

Patient sample containing compound of interest, which is reacted with added reagents and enzymes to generate a product detected spectrophotometrically

Compound of interest + Reagent A \[\xrightarrow{\text{Enzyme 1}}\] Product X

Or

Compound of interest + Reagent A \[\xrightarrow{\text{Enzyme 1}}\] Product X

\[\xrightarrow{\text{Enzyme 2}}\] Product Y

Reagents A, B and C, and enzymes 1 and 2 are all added to lead to the generation of a product that is proportional to the compound of interest or reflects the enzyme activity being measured

Reaction product results in a measurable change in light absorbance at a certain wavelength

Enzyme activity is proportional to the amount of product X or product Y, depending upon the design of the assay—and the final product is measured spectrophotometrically

**FIGURE 2–30**
Blood gas measurements

Expense: Low

Requires injection of whole blood sample into instrument with no additional manipulation

The sample for testing is arterial blood transported on ice

Sample is injected into blood gas analyzer

pH electrode measures blood pH

pCO₂ electrode—a pH electrode in a sleeve with bicarbonate—measures blood pCO₂

pO₂ electrode—detecting an electric current proportional to the amount of oxygen in the sample—measures blood pO₂

FIGURE 2–31
Urinalysis

Expense: Low

Can be completely manual or highly automated—sediment is examined microscopically which can be aided by automation in some instruments

There are two parts to a complete urinalysis

Chemical tests

Sediment analysis

Reagent pads on a dipstick change color when the compound of interest is present—after a brief dip of the stick into the urine

Reagent pads constructed to measure semi-quantitatively some or all of the following in the urine:

- Specific gravity
- pH
- White blood cells
- Nitrite
- Protein
- Glucose
- Ketones
- Urobilinogen
- Bilirubin
- Blood

Urine is centrifuged and the concentrate is examined microscopically—notable findings include:

- RBC
- WBC
- Collections of RBC or WBC in casts
- A variety of cells from the urogenital tract
- A variety of different crystals identifiable by size and shape

FIGURE 2–32
Enzyme-linked immunosorbent assay (ELISA)

**Expense: Moderate**
- To detect antibodies in the patient's serum

**Semiautomated to almost fully automated**
- To detect an antigen in the patient's serum

Antibodies are detected by binding to a corresponding antigen fixed to a surface

Antigens are detected by binding to corresponding antibodies fixed to a surface

Antibody in patient serum

Antigen fixed to surface

Detection with anti-human antibody linked to an enzyme

Add uncolored substrate for enzyme and enzyme converts it to a colored product—the darker the color, the more antibody or antigen in the patient serum

Uncolored substrate → Colored product

FIGURE 2–33
Fully automated immunoassay with all reagents in solution

Expense: Low

No antigen in sample—negative test

Antigen in sample—positive test

Free Ag-Enz allows enzyme to be active

Enzyme conjugate activity is linearly proportional to antigen concentration in sample

Enz: Enzyme  Ag: Antigen  HCG: Human chorionic gonadotropin

FIGURE 2–34
Latex agglutination

Goal of the test is to detect the presence of a compound in a patient specimen that visibly clumps latex particles.

Patient specimen which contains molecule of interest

Mix with latex beads

Antibody on beads binds the molecules of interest

Latex beads clump when molecule is present

Latex beads fail to clump when molecule is absent

FIGURE 2–35
Chromatography for separation, identification, and quantitation of substances in biologic fluids

Expense: High

Test requires manual processing and data analysis

Sample is extracted to remove extraneous molecules

Low-molecular-weight compounds

Analysis by gas chromatography (GC)

Molecules in sample may require chemical derivatization to increase volatility in gas phase

Injection of samples into instrument with column separation

Column temperature increased to separate compounds

Large molecules such as proteins and nucleic acids

Analysis by high-performance liquid chromatography (HPLC)

Mobile solvents and/or solvent pH altered to separate compounds

Compounds identified and quantitated using flame ionization (GC), spectroscopy (HPLC), mass spectrometry (GC and HPLC), or other detection method.

FIGURE 2–36
Mass spectrometry for molecular identification

Expense: High

A patient sample is processed to render it suitable for analysis

Semiautomated with high complexity of laboratory instrumentation

Molecular compounds of interest are isolated from other molecules in sample by liquid chromatography or gas chromatography

In mass spectrometer, molecule is broken into different size mass fragments creating a “fingerprint” for the molecule

The fingerprint of the molecule in the patient specimen is compared to a large library of molecular fingerprints

Molecule is identified because fingerprints match with very high percentage of agreement

FIGURE 2–37
Newborn screening by liquid chromatography/mass spectrometry (LC-MS)

Expense: High for instrumentation; moderate for test performance

After 24 h of life, heel of neonate is punctured to obtain whole blood—which is spotted onto a special card and sent to a central laboratory.

Molecular compounds of interest are extracted from a portion of the blood spot and separated by liquid chromatography.

A tandem mass spectrometer identifies the compounds of interest and quantifies the amount of each—and those compounds in higher concentrations than the reference range are “positive” in the newborn screening test.

Confirmation of positive test for compound C is performed to determine if result is true-positive.

FIGURE 2–38
Point-of-care glucose testing

**Expense: Low**

After sample is added to test strip, testing is automated

- A blood sample, which is commonly from a finger stick, is applied to a test strip
- Sample application occurs onto an absorbent pad that separates blood cells from plasma
- Glucose within plasma mixes with reagents embedded on test strip as plasma moves toward sensors
- Enzyme reactions with glucose as substrate produce electrons detected by sensors at the end of the test strip inserted into glucometer
- Sensor signal is proportional to concentration of glucose in sample, which is shown in the result display window of the glucometer

**FIGURE 2-39**
### Point-of-care immunoassay on test strip

**Cost: Moderate**

#### Negative test

**Top-down view of strip**

- Sample application spot
- Band in control region

**Band that shows test as positive**

#### Positive test

- Side view of test strip—Antigen (Ag) is present

**Sample application spot**

- Band in control region

### Manual test requiring interpretation

**Side view of test strip: Before application of sample**

- Anti-antigen antibodies fixed to strip
- Goat anti-mouse antibodies fixed to strip

**Sample application—blood or urine**

- Area has dried mouse anti-antigen antibodies with colored conjugate

**Side view of test strip after sample application—Antigen (Ag) is absent**

- Solubilizes mouse anti-antigen antibodies with colored conjugate
- No antigen in sample so—Goat anti-mouse antibodies bind mouse anti-antigen antibodies to make 1 band in control region

**Side view of test strip—Antigen (Ag) is present**

- Mouse anti-antigen antibodies fixed to strip bind Ag—and the solubilized mouse anti-antigen antibodies with the colored conjugate also bind Ag to form a colored band where fixed antibodies are imbedded onto strip

- Goat anti-mouse antibodies fixed to strip bind excess solubilized mouse anti-antigen antibodies to create a second colored band—bands shown within dashed lines

---

**FIGURE 2–40**
The Karyotype: evaluation of chromosomes

Cost: Expensive

Manual test with detailed interpretation

Human somatic cells have 46 chromosomes with 22 homologous autosomal pairs and 2 sex chromosomes—XX in females and XY in males

Blood sample collected in heparin-containing vacuum tube

Portion of sample placed into tissue culture medium with mitogens to promote lymphocyte proliferation or without mitogens

After 16–72 h of incubation time, colcemid added to arrest cell division and ethidium bromide added to elongate chromosomes

Slides are stained with Giemsa stain to produce characteristic dark and light bands

Nuclei are dropped onto slide to optimize spreading of metaphase chromosomes

Cells are ruptured while nuclei remain intact

Microscope or imaging software used to capture metaphase cells and enable karyotyping

Evaluation for numerical abnormalities and structural rearrangements by counting chromosomes and assessing the banding pattern for each chromosome

A normal male karyotype
(Courtesy of Dr Ferrin Wheeler)

Description of karyotype is total number of chromosomes, the sex chromosomes, description of any abnormality
Example: 47, XY, +21 is a male with trisomy 21.
Polymerase chain reaction with restriction enzyme digestion for detection of mutations

Expense: High

Largely manual with increasing semiautomation of methods

DNA is isolated from whole blood or tissue

DNA is denatured to separate strands

Primers for DNA fragment of interest allowed to anneal with separated DNA strands

DNA fragments of interest accumulate exponentially

Denaturation, annealing, and elongation steps repeated up to 30–40 times

DNA polymerase is added to promote elongation of DNA strand

To detect mutations in patient DNA, PCR products can be cleaved with a DNA cleaving restriction enzyme that reveals genetic difference

Example: Mutation detected by DNA fragments in polyacrylamide gel

Example: Mutation detected by DNA fragments separated by capillary electrophoresis

Wild type

Heterozygous for mutation

Homozygous for mutation

FIGURE 2–42
Comparative genomic hybridization (CGH)

Expense: High

- DNA is isolated from tumor and normal tissue from the same individual
- DNA from tumor is fluorescently labeled red; DNA from normal is fluorescently labeled green
- Tumor/normal DNA is combined and hybridized to a microarray, and then scanned with a laser

CGH can also be used to identify congenital chromosomal abnormalities. In this case, DNA from the affected individual is labeled red and control DNA from a normal individual is labeled green.

Microarray has ~1,000,000 probes covering the human genome

- If sequence is present in tumor and normal, color is yellow (mix of red and green)
- If sequence is amplified in tumor, probe is mostly red (most of DNA comes from tumor)
- If sequence is deleted in tumor, probe is mostly green (most of DNA comes from normal)

FIGURE 2–43
Small format genotyping—detect single-nucleotide polymorphisms, mutations, and insertion or deletion of bases (indels)

Expense: High

Mostly manual with some automated steps

DNA is isolated from tissue, tumor, blood

Primers that flank polymorphisms or mutations of interest (dozens to hundreds) are used to amplify these regions

A 3rd primer is designed so that it anneals immediately before the polymorphism; the next base added to the primer will be at the polymorphic position

Polymerase and ATCG are added—each of the four bases is fluorescently labeled with a different color and polymerase adds 1 base at the polymorphic position

Sample is run on a capillary sequencer and the base that was added at the polymorphic position is detected by a laser

If the patient is homozygous, 1 color will be present, and the color present indicates which base was added

If the patient is heterozygous, 2 colors will be present, and the colors present indicate which bases were added

FIGURE 2–44
Single-nucleotide polymorphism (SNP) identification by array

Expense: High

Mostly manual with some automated steps

For each SNP (single-nucleotide polymorphism, position in human genome known to have different bases in different individuals), there are 2 probes, which differ in sequence only at the polymorphic position.

Unbound DNA is washed away, and the array is scanned with a laser—if a polymorphism is present, the fluorescent labeled DNA remains bound to the array and the spot glows.

If an individual is homozygous for a position, only 1 of the probes will glow, as nothing hybridizes to the other probe.

If an individual is heterozygous at a position, both probes glow.

In this way, over 2.5 million SNPs can be analyzed on a single chip—data can be analyzed for both genotype and copy number variation.

FIGURE 2–45
Next-generation sequencing

Expense: High

Mostly manual with some automated steps

DNA is isolated from a sample and sheared

Ligation and PCR are used to add universal adaptors to each piece of DNA. This makes the sequence at the ends of every piece of DNA the same. This is called a sequencing library

Polymerase + ATCG + sequencing primer (which anneals to universal adaptors) are added. Each base is fluorescently labeled. Each base is terminated, so only 1 base can be added at a time

Billions of DNA library molecules are now attached to the flow cell

DNA library is hybridized to a flow cell, which is coated with oligonucleotides complementary to the universal adaptors

Polymerase adds the first base to every piece of DNA on the flow cell, and then the chip is scanned with a laser. Every spot, each of which is an individual piece of DNA from the sequencing library, will glow 1 of 4 colors depending on which base was added

The fluorescent marker and termination are removed from the added base, which now allows another base to be added

Polymerase + ATCG + sequencing primer are added—Polymerase adds the next base to every piece of DNA on the flow cell, and then the chip is scanned with a laser. Every spot will glow 1 of 4 colors

Repeat 200 times

Cycle 1

Cycle 2

Cycle 3

Each spot = 1 library molecule. Images are recorded in each cycle, and the color for each cycle is used to determine the base sequence. There are billions of spots on a flow cell. Thus, sequence for spot in upper left corner is A G T

The immune system is a tightly regulated network that incorporates both innate and adaptive pathways. The genes regulating the innate system are coded in the germ line. The innate immune system is not antigen specific. The cells and soluble factors of the innate system have pattern recognition receptors (PRRs, such as toll-like receptors) to common motifs on pathogens and altered self-motifs. The motifs on pathogens are called pathogen-associated molecular patterns (PAMPs). Altered self-antigens include danger-associated molecular patterns (DAMPs) as found in heat shock protein, and apoptosis-associated molecular patterns (AAMPs) as found in ds DNA, RNP, and histones. This response is rapid and there is no memory of the encounter.

The receptors on the T and B cells of the adaptive immune system are antigen or epitope specific and clonally variable, and their diversity is derived from gene recombination. The cells retain...
memory of the encounter and on subsequent engagement with that antigen, the cells exhibit more rapid and robust responses.

The immune network is tightly regulated by cells and cytokines, and a derangement in this immune homeostasis can result in immune response to self-antigens as in autoimmunity (failure of self-tolerance), or failure to recognize pathogens and eliminate them as occurs in immunodeficiency syndromes (failure of immunity). The following 2 groups of disorders are the focus of this chapter: the autoimmune diseases involving the connective tissue and the immunodeficiency diseases.

Diseases in which immune responses to self-antigens occur in the context of a genetic predisposition to disease expression are called autoimmune diseases. Some involve organ-specific pathologic autoimmunity such as Hashimoto thyroiditis and celiac disease, and these are discussed in Chapters 22 and 15, respectively. The autoimmune disorders discussed in this chapter are systemic diseases with predominant involvement of the connective tissue, manifesting clinical features including inflammation of the joints, skin, muscles, and other soft tissues (see Tables 3–1 and 3–2 and Figure 3–1).

The immunodeficiency diseases are subdivided into the relatively rare primary and the more common secondary immunodeficiency diseases. Primary immunodeficiency diseases are a direct consequence of either structural or functional derangement in the immune network. Secondary immune deficiency is the manifestation of a primary infectious disease, such as HIV infection; a malignancy as seen in lymphoma and multiple myeloma; or exposure to a therapeutic regimen such as immunosuppression or radiation.

Patterns: S, speckled. Miscellaneous causes: low titer positive ANA patterns (mostly speckled) have been described in chronic infectious diseases such as infectious mononucleosis, hepatitis C infection, HIV, subacute bacterial endocarditis, and certain lymphoproliferative diseases.
The clinical features of the disease, the morphologic pattern of the ANA test, and the serum titer of the positive ANA test are established.

If the ANA is positive, the pattern of staining suggests the differential diagnosis. The results of specific antinuclear antibody tests often establish the diagnosis. A negative ANA test can occur in rheumatoid arthritis, inflammatory muscle diseases, and when there are connective tissue manifestations in patients with selected chronic infectious diseases.

The following is an algorithm for the serologic evaluation of autoimmune connective tissue diseases.

If diagnosis is unknown and the ANA is positive, the following test panel is useful:
(a) anti-ds DNA
(b) anti-SS-A (Ro)
(c) anti-SS-B (La)
(d) anti-Sm
(e) anti-U1 RNP
(f) anti-Jo-1
(g) anti-Scl-70

For SLE
(a) If the ANA is negative, test for anti-SS-A (Ro)
(b) If the ANA is positive, tests for anti-ds DNA, anti-SS-A (Ro), anti-SS-B (La), anti-Sm and, anti-U1 RNP are informative. Anti-ds DNA titers are useful to monitor disease activity.

For Sjogren syndrome
(a) A positive ANA is supported by positive test results for anti-SS-A (Ro) and anti SS-B (La).

For polymyositis and dermatomyositis
(a) A positive ANA is supported by a positive anti-Jo-1 test result.

For mixed connective tissue disease
(a) A positive ANA is supported by a positive result for anti-U1RNP.

For Scleroderma
(a) If the ANA pattern is the speckled or centromeric, anti-Scl-70 (anti-topoisomerase 1) provides additional diagnostic confirmation.

FIGURE 3–1 An approach to the diagnosis of autoimmune disorders involving connective tissue.
**SYSTEMIC AUTOIMMUNE DISEASES INVOLVING THE CONNECTIVE TISSUE**

**Systemic Lupus Erythematous**

**Description**

Systemic lupus erythematosus (SLE) is a multisystem autoimmune disease, associated with the production of antibodies to a variety of nuclear and cytoplasmic antigens. The hallmark characteristic is the generation of antibodies to ds DNA. These antibodies complex to these self-antigens, and the ensuing immune complexes contribute to the inflammation in many organs, particularly the skin, joints, kidney, and, to a lesser extent, the cardiovascular and nervous systems, lung, and hemopoietic cells.

The disease is more common in women than in men and usually appears in early adulthood, although it is seen in children as well. It not only is more common in African Americans than in Caucasians but also has a more severe clinical phenotype with renal and vasculitic manifestations in African Americans.

The candidate genes associated with SLE include those coding for complement components C1q, C4A, C2, activating and inhibitory FcγR, interferon regulatory factor 5 (IRF5), TNF, MHC class II (DR2 and DR3), and programmed cell death PDCD1, among others.

Table 3–3 summarizes the laboratory evaluation of SLE and Table 3–4 lists the autoantibodies associated with SLE.

**Diagnosis**

According to the American Rheumatologic Association criteria for diagnosis of SLE, the diagnosis of SLE is made if 4 or more of the following 11 criteria are present at any time during the course of the disease:

<table>
<thead>

</tr>
</tbody>
</table>

Tests utilized in the initial evaluation and subsequent monitoring of patients with SLE are shown in Tables 3–3 and 3–4 and Figure 3–1.

**Sjogren Syndrome**

**Description**

Sjogren syndrome (SS) is a systemic connective tissue disease, more common in women than in men. Pathologically, it is an autoimmune exocrinopathy involving the lacrimal glands, salivary glands, and less often the pancreas. The immune inflammation of these glands contributes to the

sicca syndrome, with dry eyes (keratoconjunctivitis) and dry mouth (xerostomia) as characteristic clinical features. The disease can be primary or secondary. The primary syndrome is characterized by dry eyes, dry mouth, decreased production of tears as tested by the Schirmer test, and a lip biopsy that demonstrates inflammation of the minor salivary glands. Serologically, patients with primary Sjogren show a positive ANA, positive SS-A (Ro), positive SS-B (La), and positive rheumatoid factor (RF) in the absence of another connective tissue disease. A prospective study of 80 patients with primary SS followed for a median of 7.5 years reported the following frequencies of clinical manifestations: a) keratoconjunctivitis sicca and/or xerostomia occurred in all patients and were the only disease manifestations in 31%; b) extraglandular involvement occurred in 25%; and c) non-Hodgkin lymphoma developed in 2.5%. Secondary SS is clinically similar to the primary disorder, but it is additionally associated with clinical and serologic features of another connective tissue disease, such as rheumatoid arthritis (RA) or scleroderma.

Systemic sclerosis is characterized by excessive and often widespread deposition of collagen in many organ systems of the body. Pathologically, the hallmark is the deposition of altered collagen in the extracellular matrix and a proliferative and occlusive small vessel vasculopathy.

Diagnosis

The diagnostic features are revealed by tests that document the sicca features. The dry eyes are evaluated by the Schirmer test. This test is a measurement of tear flow over a 5-minute period. Filter paper is allowed to hang from the lateral inferior eyelid and the length of the paper that becomes wet is measured. This test is not reliable, as early in the disease there is excessive lacrimation giving a false-negative test. Demonstration of devitalized corneal epithelium due to keratoconjunctivitis is evaluated by rose Bengal or fluorescein stain. The most accurate test is the slit lamp examination of the cornea and conjunctiva. Tests for quantitating salivary secretion are not standardized and also are not specific to SS. Biopsy of the minor salivary gland in the lower lip demonstrating focal lymphocytic infiltration is a useful confirmatory test.

Table 3–5 summarizes the laboratory tests useful in diagnosis of both primary and secondary SS.

Sjogren syndrome is characterized by immune-mediated destruction of exocrine glands, particularly the salivary and lacrimal glands, with secondary development of keratoconjunctivitis and xerostomia. A positive ANA along with antibodies to SS-A (Ro) and/or SS-B (La) is a serologic feature. Transition from a polyclonal rheumatoid factor (RF) positive to a RF-negative oligoclonal or monoclonal process suggests a malignant lymphomatous transformation.
Systemic Sclerosis/Scleroderma

Description
Systemic sclerosis is characterized by excessive and widespread deposition of collagen in many organ systems of the body. The hallmark of this pathologic process is the deposition of altered collagen in the extracellular matrix. The disorder is characterized pathologically by 3 features: 1) tissue fibrosis; 2) a proliferative and occlusive vasculopathy of the small blood vessels; and 3) a specific autoimmune response associated with distinctive autoantibody profile.

The immunologic basis is not well understood, but an aberration in TGF-beta-mediated deposition of collagen has been observed. Antibodies to platelet-derived growth factor receptors have been incriminated in the development of fibrosis. Both the triggering event and genetic predisposition are not well defined. Although the common organ involved is the skin, the gastrointestinal tract, kidney, lung, and muscles are also affected as the disease progresses. Renal ischemia leading to hypertension escalates the complications of this disease. Preponderance in females is common.

Clinically there are 4 major subtypes described:

1. Diffuse cutaneous scleroderma with widespread involvement of skin and visceral organs.
2. Limited cutaneous scleroderma, in which the disease is limited to the digital extremities and face. CREST syndrome is a variant of this entity. The name is derived from its features—Calcinois, Raynaud syndrome, Esophageal dysmotility, Sclerodactyly, and Telangiectasia.
3. Localized scleroderma that affects primarily the skin of the forearms, the fingers, and later the systemic organs.
4. Overlap syndromes with features of RA or muscle involvement.

Diagnosis
Ninety percent to 95% of all patients with scleroderma have a positive ANA test. The most common pattern is finely speckled, followed by centromeric and nucleolar patterns. The ANA activity is directed against DNA topoisomerase (also known as Scl-70). A definitive diagnosis is achieved when the characteristic clinical findings are accompanied by a positive ANA test, and often confirmed by an antibody directed to Scl-70 by ELISA.

Tables 3–6.1 and 3–6.2 summarize the laboratory evaluation for systemic sclerosis/scleroderma.

Inflammatory Muscle Diseases

Description
Inflammation of the muscle leading to injury and weakness is the basis of the 3 most common but distinct diseases in this category. They are dermatomyositis (DM), polymyositis (PM), and inclusion body myositis. These diseases are more common in women, and their etiology remains unknown, although immune mechanisms have been incriminated. DM may occur as a specific entity or be associated with scleroderma or mixed connective tissue disease. Rarely, it is a manifestation of a malignancy. Skin manifestations such as a heliotrope rash, the shawl sign, and Gottron papules are common in DM. Like DM, PM may also be associated with another connective tissue disease. In addition, it may be associated with viral, parasitic, or bacterial infections. DM is characterized by immune complex deposition in the vessels and is considered to be in part a complement-mediated vasculopathy. In contrast, PM appears to reflect direct T-cell-mediated muscle injury. Inclusion body myositis is a disease of older individuals and is not associated with malignancy. It is occasionally associated with another connective tissue disease.

</tr>
</tbody>
</table>
Antisynthetase syndrome, characterized by antisynthetase antibodies that are highly specific for DM and PM, is seen in about 30% of patients with DM or PM. These patients typically experience a relatively acute onset of disease, constitutional symptoms such as fever, Raynaud phenomenon, arthritis, and interstitial lung diseases. Their hands exhibit a roughening and cracking of the radial sides of the fingers and the palm, resembling a condition found in people who labor with their hands such as mechanics, and hence called “mechanic’s hands.” HLA DR 52 has a strong association (90%) with antisynthetase antibody-positive myositis in people of both European and African descent. The antisynthetase antibodies include antibodies to aminoacyl-tRNA synthetase; antihistidyl-tRNA synthetase, also known as Jo-1; anti-signal recognition particle (SRP) antibodies directed against SRP; and anti-Mi-2 antibodies directed against a helicase involved in transcriptional activation.

### Diagnosis

Although there are several common features between DM and PM, a characteristic feature of DM itself is the heliotrope hue around the eyes. Pulmonary interstitial fibrosis is seen in about 10% of cases in both diseases, occurring in the context of antisynthetase syndromes. There are 5 distinctive features described for both of these diseases. At least 3 of the following features are essential to fulfill the clinical diagnostic criteria for each:

1. Proximal and symmetrical muscle weakness
2. History of muscle pain and tenderness on palpation
3. Electromyographic evidence of spontaneous muscle activity and myopathic changes
4. Elevated serum or plasma concentrations of muscle enzymes such as aldolase, creatinine kinase (CK), and AST
5. Muscle biopsy demonstrating cellular inflammation

The laboratory diagnosis begins with documentation of muscle inflammation and injury as shown by elevation of serum or plasma concentrations of muscle enzymes such as aldolase, CK, and AST, together with the expected inflammatory histological features on muscle biopsy. The detection of autoantibodies is found in about one third of the patients, and supports a diagnosis of inflammatory muscle disease. The antibodies are directed at tRNA synthetases. Anti-Jo-1 is such an antibody, with specificity to histidyl-tRNA synthetase. It is found in about 40% of patients with PM, and generally indicates a worse prognosis. It is also more commonly found in patients
CHAPTER 3  Autoimmune Disorders Involving the Connective Tissue and Immunodeficiency Diseases

with pulmonary fibrosis. Jo-1 is more commonly detected in cases of autoimmune myositis than in those with other causes of muscle inflammation. As with many autoimmune diseases, the integration of clinical features with laboratory findings forms the basis of definitive diagnosis. Tables 3–7.1 and 3–7.2 present the laboratory evaluation for inflammatory muscle disorders.

### Mixed Connective Tissue Disease

**Description**

The entity known as mixed connective tissue disease (MCTD) has some of the features of SLE, some of systemic sclerosis, and some of PM. The patients have variable clinical presentations with arthralgias, myalgias, fatigue, and Raynaud phenomenon. These features are superimposed on other findings that can add in over time, including malar rash, sclerodactyly, arthritis of the hands, and Raynaud phenomenon. Pulmonary manifestations occur in over 85% of these patients and include interstitial pneumonitis, pulmonary hypertension, progressive interstitial fibrosis, and, rarely, dysfunction of diaphragm and esophagus. On rare occasion, patients with MCTD develop diffuse proliferative glomerulonephritis, psychosis, or seizures.

The entity known as mixed connective tissue disorder (MCTD) has some of the features of SLE, some of systemic sclerosis, and some of polymyositis.
The appropriate constellation of clinical findings suggests the need for laboratory testing, described in Table 3–8.

### Diagnosis
The diagnosis of MCTD is largely made on the basis of the clinical features consistent with multiple autoimmune diseases. It is supported by a high titer of anti-U1 RNP in the serum.

#### Rheumatoid Arthritis
**Description**
RA is a systemic autoimmune connective tissue disorder that primarily affects the synovial joints, often starting as a synovitis. It affects 1% to 2% of the adult population worldwide, and is predominantly a disease of young women. Susceptibility and resistance to RA is associated with HLA genotypes. The criteria for diagnosis of RA were revised in 1987 to include clinical features, laboratory values, and radiographic findings. To establish a definitive diagnosis, at least 3 of the following 7 criteria must be present along with morning stiffness for a period of at least 6 weeks:

1. Arthritis in 3 or more small joints
2. Morning stiffness lasting >30 minutes
3. Arthritis of the small joints of the hand
4. Rheumatoid nodules
5. Symmetrical arthritis, often with synovitis
6. A positive test for RF
7. Radiographic changes of the affected joints

**Diagnosis**
An increased serum titer of RF has been a long-standing marker of RA, until the validation of anti-cyclic citrullinated peptide antibody (anti-CCP). This antibody not only is highly associated with RA but is also a marker for progressive and erosive joint disease. Anti-CCP is approximately 98% specific and 85% sensitive as a serum marker for RA. RF is an IgM autoantibody directed against the Fc region of IgG. While high titers of RF are associated with severe RA, it is not specific for diagnosis of RA, as it is also found in chronic infections and other connective tissue diseases. Table 3–9 summarizes the laboratory tests useful in the evaluation of RA.

#### Amyloidosis
**Description**
Amyloidosis and cryoglobulinemia (which follows) are systemic diseases resulting from the deposition in the tissues of insoluble proteins from a soluble circulating precursor. Both represent the consequences of immune dysregulation, and their diagnosis depends on laboratory evaluation and confirmation.

Amyloidosis is a heterogeneous group of diseases resulting from the extracellular deposition of low-molecular-weight fibrils from a soluble circulating precursor giving a “waxy” or “lardaceous” appearance to the infiltrated organs. Ultrastructurally, amyloid deposits are composed...
of unbranching fibrils 8 to 10 nm in width and with a molecular weight of 5 to 25 kd. At least 25 biochemically distinct forms of human amyloid protein have been identified. The 2 most common forms are primary, with amyloid light chain (AL) derived from light chains of plasma cells, and secondary, with amyloid-associated protein (AA), a nonimmunoglobulin protein. Congo red staining of amyloid deposits demonstrates a characteristic apple-green birefringence on polarized microscopy, while staining with Thioflavin T produces yellow-green fluorescence.

The classification of amyloidosis is based on whether the amyloidosis is associated with a plasma cell dyscrasia such as multiple myeloma or light chain myeloma (primary amyloidosis), or the sequelae of an infectious or inflammatory disease (secondary or reactive amyloidosis). Amyloidosis may also be classified as hereditary or acquired, localized or systemic, or by the type of fibril deposited in tissues, such as transthyretin (TTR) and Alzheimer amyloid precursor protein (APP). A partial list of the chemical classification of human amyloid is given in Table 3–10.1.

The most common form of the disease, representing 75% to 80% of the cases, is primary amyloidosis, as an acquired disorder, with multiorgan systemic involvement. Primary amyloidosis has a male to female preponderance of 2:1. Its incidence increases with age, often starting at age 40 years.

Reactive amyloidosis or type AA amyloidosis is a serious outcome of a group of diseases called autoinflammatory syndromes. This group of diseases represents too much inflammation

The diagnosis of amyloidosis is based on the histological and immunochemical demonstration of amyloid deposits in affected organs and tissues. The preferred tissue for biopsy is obtained by fine needle aspiration of the abdominal fat pad.
secondary to dysregulation of the innate immune system, in the absence of high-titer autoantibodies or antigen-specific T cells. The hereditary autoinflammatory syndromes, also known as hereditary periodic fever syndromes, represent a group of genetic disorders characterized by recurrent inflammatory episodes of noninfectious origin, often starting in childhood and persisting lifelong. These syndromes are characterized by a variety of features that include fever, abdominal symptoms, arthralgias, arthritis, lymphadenopathy, and skin manifestations. An exuberant acute phase response with elevated C-reactive protein (CRP), serum amyloid A (SAA), and leukocytosis is associated with the inflammatory clinical presentation. The soluble SAA protein is degraded to the insoluble fibrils composed of AA, which is the hallmark of secondary amyloidosis. The mutated genes in these syndromes all code for proteins that play a role in the regulation of innate immunity.

**Diagnosis**

The diagnosis of amyloidosis is based on the histological and immunochemical demonstration of amyloid deposits in affected organs and tissues. The preferred tissue for biopsy is obtained by fine needle aspiration of the abdominal fat pad. Its advantages over rectal biopsy are that multiple samples can be obtained for study, and it is less painful and invasive. Since a plasma cell dyscrasia

is commonly found in patients with amyloidosis, a serum protein electrophoresis together with a determination of serum free kappa and lambda light chains by nephelometry and a calculation of the kappa/lambda ratio is necessary to exclude a monoclonal gammopathy as the cause of the amyloidosis. Amyloid fibrils may bind to coagulation factor X causing a coagulopathy. Determination of the factor X level is important to explain bleeding tendencies in amyloidosis patients and is useful prior to biopsy of organs and tissues to identify a coagulopathy that would permit excess bleeding at the biopsy site.

To define the extent of the disease and the type of amyloidosis, the patient should be evaluated for renal, cardiac, pulmonary, neurologic, cutaneous, articular, liver, and spleen involvement. Cardiac involvement is extremely common in primary amyloidosis and much less in secondary amyloidosis. Virtually all of the familial amyloidosis manifests with nephropathic, neuropathic, or cardiopathic features. Laboratory evaluation for amyloidosis is summarized in Table 3–10.2.

**Cryoglobulinemia**

**Description**

Cryoglobulinemia refers to the presence in the serum of 1 or more immunoglobulins that precipitate at a temperature below 37°C. This precipitation is reversible, as it redissolves on warming to 37°C. The cause of cryoprecipitation remains to be determined.

Cryoglobulins are classified into 3 types. Type I consists of a single monoclonal immunoglobulin that does not have RF activity. It is typically IgM or IgG and less often IgA. Type I, also called simple cryoglobulinemia, is often associated with lymphoproliferative malignancies such as Waldenstrom macroglobulinemia or multiple myeloma. Patients with this disorder may present with features of vasculopathy involving the digits, resulting in gangrene. Type II consists of monoclonal IgM RF mixed with polyclonal IgG or IgA. The most common association for this form of cryoglobulinemia is hepatitis C infection. Type II may rarely be associated with lymphoma. Type III is also a mixed cryoglobulinemia, with polyclonal IgM RF associated with polyclonal IgG or IgA. Type III is found in patients with connective tissue disease and chronic infections. Both type II and III cryoglobulinemia patients may show fixation of complement and be associated with hypocomplementemia. Immune complex vasculitis, arthritis, neuropathy,
and renal involvement may be the presenting features in patients with type II or III cryoglobulinemia.

**Diagnosis**
When present, the cryoglobulins are quantitated using a Wintrobe tube, and the amount of cryoglobulin present is reported as a cryocrit. It is important to remember that it is not the quantity as reported by a cryocrit that is important, but the biological inflammatory properties of the cryoglobulin. This inflammatory potential is reflected by hypocomplementemia, tissue inflammation, and organ injury. With therapy, the cryocrit decreases along with mitigation of inflammatory markers such as CRP, ESR, and complement activation. When a cryoglobulin is identified, the components comprising the cryoprotein are identified by immunodiffusion and immunofixation, using specific antisera directed at the immunoglobulin isotypes and against C3 and C4. Based on the clonality and the constituent isotypes, the cryoglobulin is then categorized as type I, II, or III. **Table 3–11** summarizes the laboratory evaluation for cryoglobulinemia.

**DISEASES OF THE IMMUNE SYSTEM**

**X-linked Agammaglobulinemia**

**Description**
X-linked agammaglobulinemia (XLA), also known as Bruton agammaglobulinemia, is the prototype humoral immune deficiency. It is a disease restricted to males, and is characterized by a near total absence of B lymphocytes from an arrest in B lymphocyte development.

X-linked agammaglobulinemia (XLA) is the prototype humoral immune deficiency. It is a disease restricted to males, and is characterized by a near total absence of B lymphocytes from an arrest in B lymphocyte development.
a tyrosine kinase protein known as \textit{btk} that is essential for B-cell development. The availability of intravenous as well as subcutaneous gammaglobulin replacement therapy has improved outcome as well as longevity for these patients.

**Diagnosis**

Early diagnosis is essential to prevent infections and complications of infections, such as bronchiectasis, meningitis, bacterial sepsis, septic arthritis, and even osteomyelitis. Recognizing that B cells are CD19 and CD20 positive, a definitive diagnosis can be made at birth by enumerating B cells in cord blood by flow cytometry using monoclonal antibodies to CD19 and CD20. In children less than 6 months of age, measuring serum immunoglobulin concentration is not diagnostically useful due to the presence of transplacentally acquired maternal antibody in the blood. Thus, to establish a diagnosis in the first 6 months, it is necessary to enumerate B cells by flow cytometry. The molecular diagnosis is made by mutational analysis of the \textit{btk} gene. This is seldom needed in clinical practice as clinical features including lack of tonsils and low numbers of CD19 or CD20 cells can establish the diagnosis. Deficient expression of \textit{btk} protein can be detected by flow cytometry, a technique that can also be used for carrier detection. Table 3–12 summarizes the laboratory approach to the diagnosis of this disorder.

**Common Variable Immunodeficiency**

**Description**

Common variable immunodeficiency (CVID) affects both males and females equally. The phenotypic expression of this disease is characterized by hypogammaglobulinemia, and there are many genetic defects in the B-cell maturation pathway that apparently cause this disorder. The disease usually manifests in adult life. Unlike agammaglobulinemia, in which B cells and tonsils are absent, patients with CVID have tonsils and normal numbers of B cells in blood and lymphoid tissues. Some patients even have mediastinal and abdominal lymphadenopathy. The primary defect in CVID is that the B cells are dysfunctional, and do not differentiate into plasma cells and secrete antibody. The clinical presentation is the consequence of the hypogammaglobulinemia, namely, recurrent pyogenic infections, often of the upper and lower respiratory tracts. Lack of mucosal immunity also results in enteroviral infections and giardiasis. Autoimmune diseases such as immune hemolytic anemia, neutropenia, and pernicious anemia occur. B-cell lymphomas may manifest with time. Studies of B-cell function in CVID have revealed a subset of CVID patients who have normal or low normal IgM, IgG, and IgA but fail to make functional antibody to polysaccharide and protein antigens. Therapy with intravenous as well as subcutaneous gamma globulin has improved the clinical outcome for CVID patients.

**Diagnosis**

Table 3–13 describes the laboratory tests useful to establish the clinical diagnosis.
CHAPTER 3  Autoimmune Disorders Involving the Connective Tissue and Immunodeficiency Diseases

Hyper-IgM Syndrome

Description
Hyper-IgM syndrome (HIGM) is characterized by markedly reduced IgG and IgA, with normal to elevated IgM and normal numbers of circulating B cells. The low IgG and IgA is due to an inability of IgM-positive B cells to switch to other isotypes. The increased IgM reflects polyclonal expansion of IgM synthesis in response to infections from encapsulated bacteria. Both X-linked and autosomal recessive forms exist. The molecular causes include the X-linked loss of function mutation of the CD40 ligand (CD154) found on activated T cells, which is needed to engage with CD40 on B cells to promote the isotype switch. Other causes include loss of functional mutations of activation-induced deaminase (AID) and of uracil-DNA glycolase (UNG). These enzymes are involved in class switch recombination and in mending error-prone repair.

Diagnosis
The diagnosis is established by measuring serum IgM, IgG, and IgA along with enumerating CD19 and CD20 cells by flow cytometry. Normal or elevated IgM, with low IgG and IgA, with normal B cells, suggests the diagnosis, which can be confirmed by molecular studies.

Selective IgA Deficiency

Description
Selective IgA deficiency is the most common primary immunodeficiency syndrome. Its prevalence varies from 1 in 500 in Caucasians to 1 in 10,000 to 15,000 in Asians. The clinical picture is variable, and includes asymptomatic individuals and those with allergies, autoimmune disorders, recurrent infections, and gastrointestinal diseases. The defect is due to a B-cell differentiation arrest in the IgG to IgA isotype switch. There are low numbers of IgA-bearing B cells. Anti-IgA antibodies are found in the serum of some patients, and these individuals can experience an anaphylactoid reaction to any blood or blood product containing IgA. These patients are to be given IgA-deficient blood and blood products and washed red blood cells. Patients with pure IgA deficiency and normal IgG subclasses should not receive gammaglobulin replacement therapy as these preparations do not replace IgA and any trace IgA in the gamma globulin preparations can provoke IgA antibodies and subsequent anaphylactoid reactions.

Diagnosis
The diagnosis is made by documenting an IgA level of <5 mg/dL in the presence of normal IgG and IgM. It is important to evaluate for IgG subclasses, as subjects with IgA deficiency and a low IgG2 subclass are prone to recurrent infections. This subset of patients with IgA as well as low IgG2 subclass does benefit from intravenous or subcutaneous gamma globulin therapy. The replacement is designed to correct the IgG2 deficiency, as IgG2 is an important opsonin for polysaccharide antigens.
DiGeorge Syndrome

Description
DiGeorge syndrome is due to deletion of chromosome 22q11.2 and is part of the spectrum described as “CATCH 22” (cardiac anomalies, abnormal facies, thymic hypoplasia, cleft palate, and hypocalcemia). This deletion leads to failure of the development of third and fourth pharyngeal pouches and consequent abnormalities in the development of the thymus and parathyroid glands. Thymic dysfunction leads to T-cell abnormalities, and also B-cell dysfunction, while parathyroid abnormalities cause hypocalcaemia and tetany. Defects in the third and fourth pharyngeal pouches also result in congenital heart diseases, anomalies of the great vessels, and abnormal facies with low-set ears, fish-like mouth, and cleft palate. Patients with complete DiGeorge syndrome manifest marked defects in T-cell function and are prone to viral infections. Those with partial DiGeorge syndrome have fewer infections but have cardiac and facial abnormalities.

Diagnosis
A child with neonatal tetany and abnormal facies should be evaluated for DiGeorge syndrome by enumerating T and B cells, along with measurement of serum calcium and parathyroid hormone (PTH). The chromosome 22q11.2 deletion is documented by fluorescence in situ hybridization (FISH).

Severe Combined Immunodeficiency (SCID) Syndrome

Description and Diagnosis
As the name implies, SCID syndrome is characterized by profound defects in both cellular and humoral immunity. Affected neonates manifest severe and widespread viral, fungal, and bacterial infections soon after birth. The protection from maternal antibody is minimal, and the child fails to thrive. Respiratory failure often supervenes and is a cause of death. Patients with this disorder were the “bubble babies” decades earlier. Haploidentical, allogeneic bone marrow transplantation has altered the natural history of the disease. The path to recovery is often complicated by graft-versus-host (GVH) disease, and restitution of B-cell function is often incomplete. As a result, SCID patients may need intravenous gamma globulin to increase their antibody repertoire. Hematopoietic stem cell transplant with cytokine modulation to facilitate differentiation has been found to be superior, as there is less GVH disease.

Based on T-cell, B-cell, and NK-cell enumeration, the SCID syndrome is classified according to the position of the block/defect in T-cell and B-cell development. Currently, the spectrum of primary immunodeficiency diseases includes many underlying mutations. One group of these mutations results in different combinations of T-, B-, and NK-cell alterations, to produce SCID and related cellular immunodeficiency diseases (CID). A second group of mutations alters the amount of antibody to produce primary immunodeficiency diseases. Finally, a third group of mutations is linked to syndromes involving autoimmunity and immune dysregulation. Figure 3–2 shows 13 sites where a block in development of a T, B, or NK cell exists. The first 9 are associated with SCID or CID, and the last 4 are linked to antibody deficiency diseases. This classification permits an insight to the molecular mechanisms of the disease and provides a framework for evaluating patients for SCID.

Deficiencies of Complement Proteins

Description
The complement system of proteins and their receptors protect the host against pathogens and non-self-antigens and also abrogate the emergence of autoimmune diseases by scavenging self-antigens such as DNA so that they do not become immunogenic. Deficiencies of the complement system, therefore, result in susceptibility to infections and predispose to autoimmune diseases such as SLE. Deficiency of C3 results in increased susceptibility to infections by encapsulated, pyogenic bacteria. Deficiencies of C5, C6, C7, and C8 result in recurrent or disseminated
Neisseria infections. Deficiencies of C1q (which scavenges DNA released from apoptotic cells), C2, and C4 predispose to SLE and other autoimmune diseases. Deficiency of C1 inhibitor causes hereditary angioedema (HAE). In type 1 HAE, there is a deficiency of both the antigenic and functional C1 inhibitor protein. In type 2, the protein is antigenically normal and hence normal serum levels are noted when it is measured by an antigenic assay. However, in type 2 HAE, the protein is functionally abnormal and hence cannot inhibit the kinin, complement, kallikrein, and plasminogen pathways. This results in generation of bradykinin that causes angioedema. Lack of C1 inhibitor causes C4 consumption even in the basal state so that C4 is always low. In HAE patients with angioedema, C2 is also decreased. C3 is normal as this activation occurs in the fluid phase. Acquired C1 INH deficiency leads to a similar clinical phenotype and is called acquired angioedema (AAE). AAE is seen in lymphoproliferative states such as monoclonal B cell diseases that activate C1 leading to consumption of C1 INH via C1qrs activation. In autoimmune diseases, the autoantibody is directed to C1 INH leading to C1 INH–anti-C1 INH immune complexes that activate C1qrs. Activated C1 in the fluid phase contributes to the same sequence of events leading to bradykinin generation and angioedema. The important differentiating factor is that C1q is normal in HAE, but C1q is low in AAE. Factor I deficiency is associated with recurrent infections, and factor H deficiency with hemolytic uremic syndrome and age-related macular degeneration. Deficiency of membrane inhibitors such as decay accelerating factor (DAF or CD55) and homologous restriction factor (HRF or CD59) causes paroxysmal nocturnal hemoglobinuria.

**Diagnosis**

The traditional method to measure the functional integrity of the complement cascade was to measure the ability of this system to hemolyze antibody-coated sheep red cells in a hemolytic assay. In this test, the result is reported as titer or the concentration of serum that supports 50% hemolysis in the S-shaped titration curve (CH50 test). Serum depleted of complement due to consumption by immune complexes, and serum that is congenitally deficient in complement proteins both yield low CH50 values. This hemolysis assay has been replaced by enzyme assays.

that detect neoantigens exposed during the activation of terminal complement components. The hemolysis-based screening test for complement abnormalities in the alternative pathway is the AH50 assay. In inherited deficiencies of the complement system, specific assays for the individual complement component must be performed. Further, it must be shown that addition of that component alone will restore the full hemolytic activity. Table 3–14 provides a profile of complement activation that is useful in clinical diagnosis. Figure 3–3 provides a framework for evaluating complement deficiency diseases.

INTRODUCTION

An animal will generally accept an organ transplant from itself, but will reject a transplant from other animals, even if the donor animal is of the same species. Organ rejection is primarily a consequence of the interactions between the immune system of the transplant recipient and the histocompatibility antigens present on the transplanted cells. Clinical laboratories play an important role in the histocompatibility testing for solid organ as well as hematopoietic stem cell and bone marrow transplantation (BMT). This chapter provides a brief background to some of the issues and techniques involved in histocompatibility testing related to transplantation. Other applications of histocompatibility testing such as in the characterization of disease states (eg, HLA-B27 in ankylosing spondylitis) or before initiation of some drug therapy (eg, HLA-B*57:01 is a risk factor for hypersensitivity to abacavir) use similar techniques and are not discussed further.

The histocompatibility antigens that are the primary stimulus in graft rejection are encoded by a complex of closely linked genes called the major histocompatibility complex (MHC). In mice, these genes are located on the H2 region of chromosome 17. In humans, the analogous MHC region is located in a 4000-kb region on the short arm of chromosome 6 and encodes for the HLA system (Figure 4–1).
CHAPTER 4  Histocompatibility Testing and Transplantation

**HLA GENES AND GENE PRODUCTS**

The HLA class I region encodes for certain glycoprotein molecules that are present on all nucleated cells. The main function of the HLA class I molecules is to bind to fragments resulting from the breakdown of intracellular pathogens, such as viruses. The HLA molecule and the bound peptide are then presented on the cell surface so that an immune response can be initiated against the pathogen. Class I molecules consist of 2 noncovalently linked chains. A gene in the MHC encodes the heavy chain, and a gene outside the MHC on chromosome 15 encodes the \(\beta_2\)-microglobulin light chain. In humans, there are 3 important class I genes known as HLA-A, -B, and -C. The class II region encodes for the \(\alpha\) and \(\beta\) chains that make up the HLA-DR, -DQ, and -DP molecules.

In humans, there are 3 important class I genes known as HLA-A, -B, and -C. The class II region encodes for the \(\alpha\) and \(\beta\) chains that make up the HLA-DR, -DQ, and -DP molecules.
CHAPTER 4  Histocompatibility Testing and Transplantation

represent the HLA genotype. The alleles from both of these haplotypes are expressed on an individual's cells. This is referred to as a codominant expression of the gene. Therefore, even though there are multiple HLA genes, usually only 4 genotypes are possible in the offspring. There is a 25% chance of any 2 siblings being HLA identical and a 50% chance of the siblings sharing a haplotype.

HLA antigens and alleles are named by the World Health Organization Nomenclature Committee for Factors of the HLA System. New alleles are named on an ongoing basis as they are identified, and the number of HLA alleles has grown rapidly, with over 8000 currently listed. The DNA sequences of all recognized HLA alleles are maintained in the IMGT/HLA Database and are available online (http://www.ebi.ac.uk/ipd/imgt/hla/). Each HLA allele name follows a strict format defined by the Nomenclature Committee (Figure 4–2).

FIGURE 4–2  HLA nomenclature. The letters following the HLA prefix (eg, HLA-A) designate the gene name in the MHC system. An asterisk (*) separates the gene name from the allele name. A low-resolution DNA typing is reported at the level of the allele group with only the first set of digits (eg, HLA-A*02). This is usually the equivalent of a serologic typing result. The specific HLA protein or allele is reported by the second set of digits in a high-resolution typing (eg, HLA-A*02:01). The third set of digits is used only when necessary to indicate synonymous (silent) nucleotide substitutions, and the fourth set of digits is used when necessary to denote substitutions in noncoding regions of the gene. A letter at the end may be used to denote changes in expression (eg, N, null or not expressed). (This figure is kindly provided by Professor Steven G.E. Marsh, Anthony Nolan Research Institute, London, UK, and is from the website hla.alleles.org)
HISTOCOMPATIBILITY TESTING ASSAYS

HLA Typing
The HLA type of a potential graft recipient or donor can be determined by serology using a microlymphocytotoxicity assay. T lymphocytes are used for typing class I antigens, and B lymphocytes for typing class II antigens. The assay involves mixing known HLA typing sera with the separated lymphocytes, followed by the addition of complement. Complement-mediated lysis of lymphocytes follows when the antibody in the serum binds to the appropriate HLA antigen. The extent of cell lysis is visualized under a fluorescence microscope after exposing the cells to DNA-binding dyes such as ethidium bromide. HLA typing for class I and II antigens typically involves mixing the cells with over 200 different HLA typing sera, each in a different well of a microtiter tray.

Molecular methods allow high-resolution HLA typing at the allele level, so different alleles that cannot be distinguished by serologic assays can be identified. Such techniques also have applications in typing nonlymphocytes (eg, blasts or epithelial cells from cheek swabs) and in patients with cytopenias. One technique involves amplification of genomic DNA by polymerase chain reaction (PCR) (see Chapter 2) using primers that are locus specific (eg, all DQB1 alleles) or group specific (eg, all DR4 alleles). The amplified DNA is then hybridized with a panel of sequence-specific oligonucleotide probes (PCR-SSOP) specific for each allele or group of alleles. Even a single nucleotide mismatch will prevent the annealing of the probe. The bound probe is visualized using various methods, including autoradiography and color development, by blotting the DNA onto multiple membranes (dot blot hybridization). More commonly, the probes may be bound to a single membrane (reverse hybridization) or to groups of different colored beads (Luminex technology).

In a related technique, sequence-specific primers for an allele are used in a PCR amplification reaction (PCR-SSP). The presence or absence of PCR amplification is detected by gel electrophoresis and ethidium bromide visualization. In this technique, a positive amplification reaction signifies the presence of that specific allele.

In recent times, the PCR-SSOP and PCR-SSP methods are being replaced by sequence-based typing (SBT) methods using PCR combined with the Sanger method of DNA sequencing. The SBT methods do not always resolve sequence ambiguities that may be important in BMT, especially when the ambiguities are due to the cis/trans assignment of nucleotide bases in alleles of heterozygous individuals. Next-generation sequencing (NGS) holds the promise of resolving these ambiguities because the technique utilizes the creation of DNA libraries to produce clones of phase-defined sequences that are then sequenced in a massively parallel manner. The technique allows the simultaneous sequencing of multiple long DNA fragments in a single run.

HLA Antibody Screening
The patient’s serum can be screened for the presence of antibodies that may have resulted from prior transfusions, pregnancies, or transplants. Serum from patients is screened for reactivity against a panel of lymphocytes or purified HLA molecules from individuals (panel cells) with known HLA types. Screening can be done using either cell-based or solid-phase assays. In the cell-based assays, patient serum is mixed with different panel cells. If the cells are lysed (in a cytotoxicity assay) or if antibody binds to them (detected using a flow cytometry assay), then it is evident that the patient’s serum contains HLA antibody against the antigens expressed on that panel cell. In the solid-phase assays, HLA antigens are extracted from the panel cells. The antigens are purified and bound to a solid support, either to the wells of an ELISA plate or to colored beads that can be detected using flow cytometry or Luminex technology. Antibody binding to the molecules on the well or bead is detected using an enzyme or fluorescence conjugated anti-immunoglobulin reagent.

The number of panel cells showing lysis or antibody binding is noted, and the results are expressed as percent panel reactive antibody (PRA). Patients with a high PRA are referred to as “sensitized.” If the patient’s serum reacts with 90% of the panel cells, it is likely that the patient will have to wait longer for a compatible donor than someone who shows a PRA of 0% (ie, no HLA antibody). Identification of the HLA antigen specificity of the antibody is an important feature of
the antibody screening assays, and may reduce unnecessary crossmatches between patients who have antibodies against specific HLA antigens and donors who are positive for those antigens. Knowledge of antibody specificity can also increase opportunities for identifying compatible donors for these difficult-to-match patients. Highly sensitized (high PRA) patients may also be managed differently posttransplant since they have a higher risk of rejection. Pretransplant screening for HLA antibodies is also indicated in patients undergoing autologous stem cell transplants, since posttransplant patients with a high PRA are more likely to become refractory to platelet transfusions and may require careful observation regarding their need for HLA-matched platelets.

**Crossmatching**

The lymphocyte crossmatch is a critical step, especially before renal transplantation. It is also important in sensitized patients who are undergoing a heart or lung transplant. In this assay, the graft recipient’s serum is mixed with donor lymphocytes (similar to that shown for red blood cells in Chapter 2 under Blood Crossmatch). If the recipient has preformed HLA antibodies against donor antigens, the cells will be lysed, the crossmatch is considered positive, and the transplant will likely not be done. The test may be performed using a variation of the microlymphocytotoxicity assay that is used for HLA typing. In this test, antihuman globulin (AHG) is added to the microtiter wells after mixing the serum with the lymphocytes, which greatly increases the sensitivity of the assay. The crossmatch may also be performed by measuring antibody binding to cells by flow cytometry.

**HISTOCOMPATIBILITY REQUIREMENTS FOR SOLID ORGAN TRANSPLANTS**

In general, HLA matching is not an absolute requirement with respect to solid organ transplants (Table 4–2). It is usually a requirement for BMT. The application of HLA typing, crossmatching, and antibody screening in histocompatibility testing prior to transplantation of specific organs or tissues is described hereafter.

**Kidney**

Renal transplantation from living donors, whether HLA matched or unmatched, is preferable to kidney transplantation from deceased donors. The half-life of a transplanted deceased donor kidney is about 8 years, as compared with 12 and 26 years for kidneys matched at 1 or 2 haplotypes from living donors. In the United States, nearly 35% of the kidney transplants are from living donors, including genetically unrelated donors such as spouses or friends. In a large multicenter study involving primary cadaveric renal transplants, multiple factors were shown to influence the outcome. These included the age of donor and recipient, presence of diabetes in the recipient,

*HLA matching preferable but not required.
the cause of the donor’s death, cold ischemic time of the donated kidney prior to transplant, the transplant center, and matching for HLA antigens. The advantages of HLA-matched transplants include a reduced need for antirejection treatment and posttransplant dialysis, as well as significantly improved long-term survival. Other important predictors of outcome are ABO blood group compatibility, PRA, and crossmatch between donor lymphocytes and recipient serum. A positive crossmatch is usually a contraindication to transplant. However, techniques to remove recipient circulating HLA and/or ABO antibody have been recently developed, allowing successful transplantation with previously incompatible kidneys.

Liver

HLA matching does not appear to correlate with better outcomes in liver transplantation. There are conflicting reports regarding the importance of a negative crossmatch in the pretransplant setting, but donor-specific HLA antibodies are not a contraindication to transplantation. ABO matching, in contrast, is associated with better outcomes in both adult and pediatric populations.

Heart

The benefits of HLA matching in heart transplantation are difficult to evaluate because there are few studies that utilize prospective HLA matching. The usual priorities in cardiac transplantation are short ischemia time for the donated heart prior to transplant (<4 hours), heart size, and blood group matching. Most centers screen for HLA antibodies prior to transplant surgery and perform, when possible, a prospective crossmatch using donor cells only on sensitized patients. The presence of HLA-specific antibodies and a positive crossmatch against donor cells are generally accepted to be associated with an adverse outcome.

Lung

While there may be a small survival advantage with HLA-matched lung transplants, there is no consensus on the hierarchical importance of the various HLA loci. Lungs are allocated on the basis of ABO compatibility and size. Similar to heart transplant patients, crossmatches are usually done only on patients known to have HLA antibody.

Pancreas

Pancreata are transplanted based on ABO compatibility. HLA antibody screening is performed on transplant candidates, and a positive crossmatch is usually a contraindication to transplantation with that donor. Patients with pancreas-only transplantation have a lower survival rate than those undergoing combined pancreas and kidney transplantation. Most pancreata are transplanted in patients undergoing kidney transplants for diabetic renal failure. Evidence suggests that the kidney–pancreas transplant combination is associated with a long-term reduction in mortality, as compared with renal transplant only, in end-stage diabetic renal disease.

Cornea

The cornea is the most commonly transplanted tissue. There is no convincing evidence for the utility of HLA and ABO group matching for corneal transplants. However, the long-term graft survival is approximately 50% and rejection remains the most common cause of graft loss. Because corneal rejection is not life-threatening, the routine use of systemic immunosuppression for prevention of rejection is not a consideration.

HEMATOPOIETIC STEM CELL TRANSPLANTATION

Hematopoietic bone marrow/stem cell transplantation is a therapeutic option in which normal hematopoietic stem cells are used to replace abnormal hematopoietic stem cells or to reconstitute the bone marrow of patients undergoing high-dose cytotoxic therapy for
malignancy. The hematopoietic stem and progenitor cells can be harvested from the bone marrow under general anesthesia or from the peripheral blood after giving the donor multiple doses of growth factors/cytokines such as granulocyte colony-stimulating factor (G-CSF) or granulocyte–monocyte colony-stimulating factor (GM-CSF).

HLA matching is usually a requirement for allogeneic stem cell transplantation. A positive crossmatch between donor and recipient is a strong predictor of graft failure, but because most patients and donors are HLA matched, this is rarely a concern. Recently, success has been obtained in cases involving partially mismatched BMT, which has increased transplantation opportunities for many patients.

In the past, serologic techniques were used extensively for HLA typing in BMT. As noted earlier, it is now known that the number of identifiable serologic specificities at any locus is far less than the number of true alleles at that locus (Table 4–1). Individuals who appear to be HLA matched after serologic typing may in fact have some mismatched alleles. Patients transplanted with genotypically HLA-matched marrow from siblings or unrelated individuals have a graft failure rate of approximately 2%. The risk of graft failure is much higher in the presence of a mismatch of 2 or more class I alleles.

The widespread availability of high-resolution allelic typing methods that allow better matching of donors with recipients has resulted in improved outcomes.

A substantial portion of this chapter also appeared previously in Clinical Laboratory Reviews (a newsletter publication of the Massachusetts General Hospital, 2000;8:3).

LEARNING OBJECTIVES

1. Determine if an organism of interest is a bacterium, fungus, parasite, or virus and learn how it is further classified among related organisms.

2. Learn the organisms that produce the commonly encountered and better characterized infectious diseases.

3. Distinguish pathogenic organisms from those found in normal flora.

4. Learn the laboratory test results associated with the individual infectious diseases and how they are used in establishing the diagnosis.

INTRODUCTION

Humans live in a world of microbes. Many types of microbes are part of the normal human flora and rarely cause disease. Others have a greater potential for virulence and can cause disease depending on complex interactions between the host and the microbe. A small group of organisms are highly virulent and usually cause disease whenever they infect humans. This chapter on infectious diseases and clinical microbiology focuses on common pathogens and frequently encountered clinical syndromes. Infectious agents include a daunting array of viruses, bacteria, fungi, protozoans, and helminths. Table 5–1 provides information on the basic microbiology and clinical significance of common pathogens. The organisms are grouped based on shared properties because these are often relevant to the diagnostic process.

Because of the large number of potential pathogens, it is not technically possible, practical, or cost-effective to attempt to rule out all of them in each patient who may have an infection. It is, therefore important for the clinician to know what organisms are most likely in a particular patient and whether routine diagnostic tests will detect them or whether specialized tests are needed. Identification of the causative agent is usually important for determining the most appropriate therapy. It can also have infection control or public health implications. The clinical findings are the first major clues in determining the site of infection and identifying a pathogenic organism. For example, a cough is usually indicative of a process in the respiratory tract while pain on urination is a clue to a urinary tract infection (UTI). Radiographic studies can further clarify the type of process and may point to specific categories of organisms.

Often, a single species of microbe can cause multiple syndromes. Conversely, a single syndrome may be caused by multiple organisms. This can lead to a potentially vast array of diagnostic possibilities. In order to determine the diagnosis in a timely and cost-efficient manner, it is essential to take into consideration the clinical setting. For example, the organisms responsible for a community-acquired pneumonia are usually different from those that cause nosocomial pneumonia. If the patient is immunosuppressed, this further enlarges the list of potential organisms. It also matters whether the immunosuppression is due to decreased cell-mediated immunity, for example, due to HIV infection or inhibitors of tumor necrosis factor (TNF), versus neutropenia secondary to chemotherapy because each has its own associated group of opportunistic infections. Other underlying conditions such as diabetes or sickle cell disease, or the presence of prosthetic devices, are associated with specific infections. A history of travel or exposure to arthropod vectors may raise the possibility of additional organisms.

The organization of this chapter reflects the common associations between selected organisms and the site of infection. The discussion of a particular organism in a specific anatomic site in this chapter does not imply that infection by that organism is restricted to that location. Several infectious diseases, such as viral hepatitis (see Chapter 16) and Helicobacter pylori infections (see Chapter 15), are presented elsewhere in this book because these infections are intimately associated with a specific organ or tissue. The organisms and diseases selected for presentation in this chapter were chosen primarily by their incidence, with a preference for common infections. Many lower-incidence infections also have been included because they are often within a differential diagnosis, new information on their diagnosis and treatment is emerging, or they can be overlooked if appropriate tests are not requested. The chapter focuses on infections commonly encountered in the United States, although several travel-associated infections are discussed.

A general clinical approach to the patient with an infectious disease is diagrammed in Figure 5–1.

*Continued next page—*
List clinical signs and symptoms to identify specific organs and tissues likely to be infected.

Collect appropriate samples for analysis (see Chapter 2) from site of infection.

Order appropriate tests to detect the most likely infectious agents (see Tables 5–3 to 5–42). This may include Gram stain and bacterial culture for common infections and/or specialized tests such as fungal culture, nucleic acid amplification tests for viral agents, microscopy for parasites, or serologic tests, depending on the differential diagnosis.

Begin empiric treatment if necessary with agents effective against most likely pathogens.

The laboratory isolates/identifies pathogenic organism(s). If more than 1 organism is detected in the sample, determine the pathogen(s) based on clinical correlation and knowledge of normal flora.

The laboratory performs tests for antibiotic susceptibilities of pathogenic organisms. When these results become available, modify treatment if necessary to target the pathogenic organism(s). Susceptibility tests are widely used for bacterial infections but are less frequently used for fungal, viral, and parasitic infections.

FIGURE 5–1 A general clinical approach to the patient with an infectious disease.
LABORATORY TESTS FOR INFECTIOUS AGENTS

The laboratory diagnosis of infectious disease utilizes 5 distinct types of tests: direct examination, culture, antigen detection, nucleic acid detection, and serology. Each of these tests has strengths and weaknesses. The types of test(s) that are used in a specific case depend in large part on the organisms that are in the differential diagnosis, as well as the type of specimens that are available. See Chapter 2 for illustrations of these laboratory methods.

Direct Stains

Direct examination involves preparing a smear of the specimen and then using an appropriate staining technique to detect the relevant microorganisms. The Gram stain is rapid and detects most types of bacterial pathogens if they are present in sufficient numbers. It provides a preliminary characterization in terms of the Gram reaction, that is, positive or negative, as well as the morphology (cocci, coccobacilli, or bacilli) and arrangement of the cells (individual cells, pairs, chains, or clusters). It also provides information on the host response, for example, the presence or absence of neutrophils. This stain is routinely performed on most specimen types including respiratory specimens, sterile fluids, tissue biopsies, wounds, and abscesses. It is not routinely performed on stool because of the large numbers of normal flora, urine because similar information is available from the urinalysis, and blood because of the small number of organisms typically found in cases of bacteremia. The analytic sensitivity of the Gram stain is relatively low because the observation of an average of 1 organism per oil immersion field corresponds to a concentration of $10^5$ organisms per milliliter in the specimen. The sensitivity can be increased by concentration of the specimen through centrifugation. Other direct stains include acid-fast stains for mycobacteria and calcofluor white for fungi. Wright stains of peripheral blood are used to detect Plasmodium and Babesia infections. Routine hematoxylin and eosin stains as well as Gram, acid-fast bacteria (AFB), and Gomori methenamine silver (GMS) stains can reveal the presence of microorganisms in paraffin-embedded tissue in the surgical pathology laboratory.

Culture

Isolation of organisms in pure culture continues to be the mainstay of microbiologic diagnosis. In general, culture is very sensitive and specific and remains the “gold standard” for diagnosing many types of infection. Culture provides relatively rapid detection (within usually 1-3 days) of a wide array of organisms that are then available for definitive identification and antimicrobial susceptibility testing. One of the great advantages of culture assays is that microbiology laboratories routinely inoculate a combination of nonselective and selective media that will support the growth of many types of pathogenic bacteria. The person ordering the test does not need to specify which organism or organisms are suspected of causing the infection. A clinician who submits a blood-culture bottle does not have to order a Staphylococcus culture, a Streptococcus culture, a gram-negative rod culture, etc. Nonetheless, it is essential to remember that routine cultures only detect typical bacteria. If other classes of agents, such as mycobacteria, fungi, parasites, or viruses, are in the differential diagnosis, then the clinician must request the appropriate tests. For example, mycobacteria and fungal cultures utilize media designed to inhibit the growth of routine bacteria and they also require prolonged incubation.

Identification of Organisms From Positive Cultures

The majority of bacterial pathogens are routinely identified by the presence of specific combinations of phenotypic traits including production of enzymes, such as catalase, coagulase, oxidase, and urease, ability to ferment or utilize different types of sugars, and additional metabolic reactions. Many of these individual tests have been combined into commercial identification kits. In contrast, slow-growing organisms, such as mycobacteria, and bacteria that are difficult to identify with traditional biochemical methods are now often identified by nucleic acid amplification and sequencing of conserved genes such as 16S ribosomal RNA or RNA polymerase. Yeasts are generally identified with biochemical tests similar to those used for bacteria. Finally, identification of molds is based on colonial and microscopic morphology.
More recently, commercial identification systems have been developed that use matrix-assisted laser desorption-ionization time-of-flight (MALDI-TOF) mass spectroscopy (MS) to generate protein spectra that can be compared with databases to identify bacteria and other microbes. The advantage of MALDI-TOF/MS is that it requires few reagents and can identify organisms in minutes as opposed to the 12- to 24-hour incubations required for most biochemical panels.

**Susceptibility Testing**

Once an organism has been identified in the clinical microbiology laboratory, the second major task, in most cases, is determining the organism’s antibiotic susceptibility profile. Susceptibility tests involve the measurement of the minimum inhibitory concentration (MIC), the lowest concentration of antimicrobial agent that inhibits the growth of the organism. The reference method is the microbroth dilution technique. The MICs are then interpreted as sensitive, intermediate, or resistant according to tables of interpretive breakpoints that are related to therapeutically achievable serum levels for each antibiotic. Other susceptibility methods such as disk diffusion (measuring the diameter of the zone of inhibition surrounding an antibiotic-containing disk) can be correlated with the results of the broth dilution technique.

Susceptibility testing has become increasingly complex due to the widespread dissemination of increasingly resistant pathogens that include methicillin-resistant *Staphylococcus aureus* (MRSA); vancomycin-resistant enterococci (VRE); and multidrug-resistant strains of *Klebsiella pneumoniae*, *Pseudomonas aeruginosa*, and *Acinetobacter baumannii*. These organisms harbor a variety of resistance mechanisms that include altered penicillin-binding proteins, extended-spectrum beta-lactamas, carbapenemases, inducible clindamycin resistance, and multidrug efflux pumps. While molecular methods can be used for rapid detection of specific resistance genes, such as the *mecA* gene in MRSA and the *vanA* and *vanB* genes in VRE, most susceptibility testing depends on phenotypic (MIC-based) methods that require overnight incubation.

**Antigen Detection**

Antigen detection tests do not require the growth of microorganisms. Therefore, they have the potential to provide rapid detection of infectious agents. Immunoassays that detect soluble antigens vary in speed, complexity, sensitivity, and specificity. Usually there is a trade-off between simplicity and sensitivity. Immunochromatographiic assays require very few procedural steps and are the basis of many rapid point-of-care tests. These assays are less sensitive than traditional solid-phase enzyme immunoassays (EIAs) that are used for batch testing in the laboratory. Unlike culture-based assays, an immunoassay can only detect the organism that binds to the reagent antibodies; a separate assay must be performed for each organism. Immunoassays generally exhibit good but not perfect specificity. Furthermore, they cannot distinguish viable from nonviable organisms. Direct or indirect fluorescent immunoassays utilize microscopy to identify organisms that bind the reagent antibody. These assays often have high sensitivity and specificity compared with other types of immunoassays, but they require extensive training to insure proper interpretation.

**Nucleic Acid Amplification**

The introduction of nucleic acid amplification techniques (NAATs) has revolutionized several areas of infectious disease testing including HIV viral load testing, diagnosis of Herpes simplex virus (HSV) encephalitis, and rapid detection of MRSA. They are particularly valuable for detecting difficult-to-grow or slow-growing organisms that may be present in small numbers. NAAT tests have the potential for very high sensitivity and specificity. However, as with antigen tests, they can only be used to diagnose infections caused by organisms that the assay detects. Current technology is not at the stage where it can eliminate the use of traditional culture methods in the routine bacteriology laboratory. Nonetheless, this is a rapidly changing field as illustrated by the widespread adoption of multiplex NAAT assays that can simultaneously detect a panel of common respiratory viruses.
Serology
Serologic tests detect host antibodies that are produced in response to infection with a particular infectious agent. The most important limitation of these assays is that antibody is usually not detectable early in the course of infection. Even if antibody is detected, it may represent a past infection. Serologic diagnosis usually requires demonstration of seroconversion, a 4-fold rise in IgG titer between sequential specimens, or a positive IgM assay. While the latter is usually thought of as a marker of acute infection, IgM can persist for 6 to 12 months. For the reasons outlined above, serologic assays are mainly used to diagnose infections that cannot be detected using more direct methods.

SEPSIS AND BLOODSTREAM INFECTIONS

Bacteremia
Description
Normally the blood is sterile. Infection in any of the organs or tissues can result in entry of bacteria into the circulation. Replication of bacteria in the blood can contribute to the signs and symptoms of sepsis (eg, fever, tachycardia, leukocytosis, and hypotension) and may lead to dissemination of the organism to other tissues and organs; however, patients can be septic without having demonstrable bacteria in their blood. Bacteremia is often described as transient, intermittent, or continuous based on the number of positive specimens. Transient bacteremia occurs when small numbers of a commensal organism present on a mucosal surface gain access to the bloodstream. These infections are usually not clinically significant when they occur in an otherwise healthy host. Intermittent bacteremias are usually associated with a sequestered infection somewhere in the organs or tissues (eg, an abscess). Continuous bacteremias are associated with an intravascular focus of infection. Examples include endocarditis or an infected vascular catheter.

Diagnosis
Blood cultures are routinely collected as part of the diagnostic evaluation of patients who present with signs and symptoms of sepsis or disseminated infection. To maximize sensitivity and specificity, it is recommended that 2 to 3 sets of blood cultures be collected per septic episode. Most hospitals use continuous blood culture systems that utilize colorimetric, fluorescent, or manometric methods to detect bacterial growth. Positive bottles are then subcultured to agar plates for further evaluation of the organisms.

To identify intermittent bacteremias, the timing of the blood collection is important to maximize the likelihood of finding organisms while they are in the blood (see the section on sample collection in microbiology in Chapter 2). Ideally, blood from patients with intermittent bacteremias is collected during the hour before a temperature spike, but this is not practical because the febrile episodes are often not predictable. It is common practice for blood to be collected at 30- to 60-minute intervals (if possible) when a febrile patient is suspected of having an intermittent bacteremia. As one might expect, one is much more likely to detect a continuous bacteremia in the first blood culture than to detect an intermittent bacteremia.

A major problem in the interpretation of the blood culture results is incidental contamination of the specimen with the normal bacterial flora from the skin.
bacteria are often thought of as nonpathogenic, it is important to remember that they can cause clinically significant infections, particularly in immunosuppressed patients and in patients with intravascular catheters or prosthetic devices. The isolation of the same skin flora organism in 2 separately collected specimens increases the probability that it represents a clinically significant bacteremia.

To avoid the problem of contamination of the blood culture bottles with skin organisms, meticulous preparation of the skin with a bactericidal agent is necessary. The number of blood cultures required for detection of a pathogenic organism is determined by the volume of blood collected per bottle, the timing of the blood collection, the type of organism producing the infection, and previous antibiotic exposure. Three or more blood culture collections may be required to document the presence of certain organisms.

### Infections Caused by *Rickettsia*, *Ehrlichia*, and Related Organisms

**Description**

*Rickettsia*, *Ehrlichia*, and *Anaplasma* are obligate intracellular bacteria that cannot be detected in routine bacterial cultures. These organisms are transmitted to humans by ticks; therefore, the risk of acquiring these infections depends on the geographic distribution of the tick vectors and the time of year (see Table 5–4).

*Rickettsia rickettsii*, the agent of Rocky Mountain spotted fever (RMSF), is mainly transmitted by the dog tick (*Dermacentor variabilis*) and infects endothelial cells. The resulting vascular injury elicits a widespread vasculitis, consisting of vasodilation with perivascular edema, and at times complicated by thrombosis and hemorrhage. Erythrocytes extravasating into the dermis form nonblanching petechial or purpuric lesions. The characteristic rash is often absent during the early stages of infection, and the infection can progress to a life-threatening encephalitis if not promptly treated.

*Ehrlichia chafeensis* is transmitted by the lone star tick (*Amblyomma americanum*) and infects monocytes. Patients present with nonspecific findings including fever, leukopenia, thrombocytopenia, and/or elevations of hepatic enzymes. Similar clinical manifestations are seen with *Anaplasma* (formerly *Ehrlichia*) phagocytophilum that is transmitted by deer ticks (*Ixodes* spp.) and infects granulocytes.

**Diagnosis**

None of these agents can be cultured on artificial media. RMSF is usually diagnosed retrospectively with serologic tests; however, this should not delay treatment that should be initiated based on clinical findings and potential history of exposure. If the rash is present, organisms can be
demonstrated by immunohistochemical staining of a skin biopsy in 70% of cases. Examination of peripheral blood smears in patients with *Anaplasma* can reveal the presence of organisms within inclusions in neutrophils, but many cases are negative. *Ehrlichia* infects monocytes but is rarely observed in peripheral blood smears. Polymerase chain reaction (PCR) of blood and/or serologic tests are the best methods for diagnosing *Anaplasma* and *Ehrlichia* infections.

**Fungemia**

**Description**

Yeast belonging to the genus *Candida* are a major cause of hospital-acquired bloodstream infections. These organisms are frequently part of the oral and gastrointestinal flora. Treatment with broad-spectrum antibiotics that disrupt the normal bacterial flora, the presence of intravenous catheters, and neutropenia all predispose to the development of candidemia. *Cryptococcus neoformans* and *Histoplasma capsulatum* are important causes of fungemia in patients with markedly depressed cell-mediated immunity (*Cryptococcus* is further discussed in the section “Chronic Meningitis” and *Histoplasma* is further discussed in the section “Infections of the Lung and Pleurae”). Although molds such as *Aspergillus* spp. can cause disseminated infections in immunosuppressed patients, they are rarely detected in the bloodstream.

**Diagnosis**

Candidemia can usually be detected with routine blood cultures. Specialized techniques (eg, lysis–centrifugation cultures) are usually required to detect *H. capsulatum* and may
enhance the detection of \textit{C. neoformans}. Immunoassays that detect antigens produced by \textit{H. capsulatum} and \textit{C. neoformans} are also used to diagnose disseminated infections caused by these organisms.

**Parasitic Infections of the Blood**

**Overview**

Several vector-borne parasites can infect the blood. These include protozoans such as \textit{Plasmodium} spp. (malaria), \textit{Babesia} spp., and \textit{Trypanosoma} spp., and nematodes such as the agents of lymphatic filariasis. \textit{Plasmodium} infections are an important cause of nonspecific febrile illnesses in returning travelers, and \textit{Babesia} infections are endemic in the United States; these infections are discussed below. Other blood parasites are uncommon in the United States.

**Malaria**

**Description**

Malaria is one of the largest causes of mortality and morbidity in the world. Individuals who travel to areas where malaria is endemic and develop fever within weeks of return should be suspected of suffering from malaria.

There are 4 species of \textit{Plasmodium} that cause most cases of human malaria. These parasites are transmitted by \textit{Anopheles} mosquitoes that are widely distributed throughout Africa, Asia, and Latin America. The most dangerous of the 4 species is \textit{Plasmodium falciparum}. This organism can achieve very high levels of parasitemia and adheres to capillary endothelium, and this can lead to severe organ damage. \textit{P. falciparum} infection may be fatal within days. \textit{P. vivax} and \textit{P. ovale} are morphologically similar and generally cause less severe infection, but unlike \textit{P. falciparum}, they can establish persistent infection and cause relapses several months after the initial infection. \textit{P. malariae} is the least virulent species and can cause low-level infection that may cause few symptoms, but it can persist for years. \textit{P. knowlesi}, which infects monkeys, can also cause human infections.

**Diagnosis**

Currently, the diagnosis of malaria and the identification of each of the 4 species of \textit{Plasmodium} responsible for malaria are based on the microscopic examination of stained erythrocytes in thick and thin blood films. These organisms have maturation cycles involving a variety of specific structures in the RBC, including ring trophozoites, growing trophozoites, mature schizonts, and gametocytes. The stippling of the RBCs with different dot patterns is also important in differentiating between the 4 species. Thus, the size and shape of the various malarial forms, their alteration of RBC morphology, and the stippling pattern in the RBCs provide the identification of the particular type of malaria. Quantitation of the level of parasitemia is also important. Marked parasitemia is a poor prognostic sign for \textit{P. falciparum} infection. However, ill patients may have relatively low levels of parasitemia due to trapping of organisms in capillaries. PCR is starting to be used for the diagnosis of malaria and is particularly useful when low levels of parasitemia make it difficult to identify individual species. A rapid immunodiagnostic test for malaria may also be useful in settings where microscopy is not immediately available. Table 5–5 summarizes the relevant laboratory information for the diagnosis of malaria.

**Babesiosis**

**Description**

\textit{Babesia} species are protozoa that, like \textit{Plasmodium} species, infect erythrocytes. They are delivered to the infected host by the same tick (\textit{Ixodes}) that transmits the agent of Lyme disease and human granulocytic anaplasmosis. Babesiosis mimics malaria in that it causes hemolysis, fever, anorexia, and hemoglobinuria. In the United States, \textit{B. microti} is responsible for most cases of human babesiosis. In Europe, \textit{B. bovis} and \textit{B. bigemina} have been implicated as agents of human disease. Babesiosis occurs mainly in the Northeast and upper Midwest in the United States. It affects
patients of all ages, but most cases occur during the sixth and seventh decades of life. The infection from *Babesia* tends to be self-limited. In most cases, it lasts from weeks to months, following an incubation period of 1 to 6 weeks. Mild symptoms, including malaise, fever, and headache, characterize the disease in normal hosts, but asplenic patients often develop severe infections with high levels of parasitemia.

**Diagnosis**

The laboratory diagnosis rests upon the identification of the *Babesia* organisms inside erythrocytes in stained thick and thin peripheral blood smears. There are a number of morphologic features that differentiate *Babesia* from *Plasmodium*. Despite its relative shortcomings, serologic testing for *B. microti* can be performed as noted in Table 5–6. The level of parasitemia with *Babesia* does not always correlate with the severity of symptoms.

**Viral Infections of the Blood**

**Overview**

Many viruses such as varicella zoster virus (VZV), measles, enteroviruses, and arboviruses (such as West Nile virus) exhibit a viremic phase. These viruses also exhibit organ-specific manifestations and are discussed in other sections of this chapter. Cytomegalovirus (CMV), Epstein–Barr virus (EBV), and parvovirus B19 are discussed below because they are common viruses that can have a direct effect on the blood.

<th>Results/Comments</th>
</tr>
</thead>
<tbody>
<tr>
<td>Identification of organisms within RBC in blood smears</td>
<td>The first-line test in the diagnosis of malaria; for best results, blood should be collected from the patient during or after a febrile episode and before the administration of antiparasitic medications; to rule out malaria, it is recommended that negative results be demonstrated in blood samples collected every 6-8 h for 24 h. Preparation of smears: thick and thin blood smears should be prepared; thick smears allow for a rapid examination of a relatively large volume of blood and have approximately a 10-fold increase in sensitivity over thin smears; thin smears allow for superior preservation of morphology and are needed for species determination; the best stain is the aqueous Giemsa stain buffered with phosphate to pH 7.2. Reading of smears: no single criterion except for the crescentiform (banana-shaped) gametocyte of <em>Plasmodium falciparum</em> is pathognomonic; multiple morphologic criteria are used to make the diagnosis of malaria and determine speciation of the <em>Plasmodium</em>; it is very difficult to speciate when mixed <em>Plasmodium</em> infections occur; PCR can be used to confirm identification when morphology is not definitive.</td>

Infectious Mononucleosis/Epstein–Barr Virus

Description

Most cases of mononucleosis are caused by EBV, a member of the herpesvirus family that infects B lymphocytes and causes them to proliferate. This in turn stimulates the proliferation of cytotoxic T cells that control the active infection but do not eradicate the latent state. Infection with EBV is extremely common, and most individuals have asymptomatic infections. Patients with infectious mononucleosis typically present with fever, sore throat, and enlarged cervical lymph nodes.

In addition to mononucleosis, EBV is associated with 2 types of human tumor (Burkitt lymphoma and nasopharyngeal carcinoma) and is responsible for lymphoproliferative disorders in patients with severe immunosuppression following organ transplantation or AIDS. It also causes oral hairy leukoplakia in HIV-infected patients.

Diagnosis

Large atypical lymphocytes (cytotoxic T cells) are usually present in peripheral blood smears of patients with infectious mononucleosis caused by EBV, but they are also found in many other infections. The diagnosis of EBV-associated infectious mononucleosis is usually confirmed by a positive serum heterophile antibody test that detects the presence of antibodies that agglutinate horse or cow erythrocytes. The heterophile test is often negative in young children or in patients with atypical presentations; EBV-specific serologic tests are especially important in establishing the diagnosis in these situations. Quantitation of EBV DNA in peripheral blood is important in the diagnosis and management of EBV-associated lymphoproliferative disease in solid organ and bone marrow transplant recipients.

The use of laboratory tests in the diagnosis of infectious mononucleosis is shown in Table 5–7.

Cytomegalovirus

Description

CMV causes several clinical syndromes. It infects leukocytes, where it remains latent in immunocompetent individuals but readily reactivates in immunosuppressed individuals. CMV is a leading cause of opportunistic infections in transplant recipients and AIDS patients. In transplant recipients, it often presents as a nonspecific febrile illness, but it can also cause more invasive infections including esophagitis, hepatitis, colitis, pneumonitis, and retinitis, particularly in severely immunocompromised patients. CMV is also the most common congenital viral infection. It affects

### Table 5–7 Evaluation for Infectious Mononucleosis

</thead>
<tbody>
<tr>
<td>Heterophile antibody tests</td>
<td>Heterophile antibodies are IgM antibodies reactive with antigens on the cells from multiple species, and on this basis are termed heterophilic; they are detected in agglutination assays with horse or sheep RBCs or by their capacity to induce an agglutination response on antigen-coated latex particles; in infectious mononucleosis, the heterophile antibody test result is positive approximately 1 week after the symptoms first appear; the highest titers appear in the second to third week of the illness; relatively high titers persist for up to 8 weeks</td>
</tr>
<tr>
<td>Antibodies to EBV-specific antigens</td>
<td>Although heterophile-negative infectious mononucleosis is uncommon, it does occur, mostly in young children; in these cases, a characteristic clinical picture and the presence of IgM against the EBV viral capsid antigen (VCA-IgM) or a rising titer of VCA-IgG can confirm acute infection, whereas a negative VCA-IgM and positive VCA-IgG and positive EBNA antibodies (EBV nuclear antigen) indicate past infection</td>
</tr>
<tr>
<td>WBC differential</td>
<td>Patients with mononucleosis typically have a mild-to-moderate leukocytosis after the first week, with more than 60% of the WBCs as lymphocytes and 10%-20% of all lymphocytes being atypical; the maximum percentage of atypical lymphocytes appears between days 5 and 10 after the onset of symptoms, with a decrease to normal by approximately 3 weeks in most patients</td>
</tr>
</tbody>
</table>

EBV, Epstein–Barr virus.
approximately 40,000 infants born each year in the United States. Hematogenous spread appears to be responsible for transmission of the virus to the fetus. Most congenital infections occur when the mother has a primary CMV infection during the pregnancy. Neonates can also acquire the infection from maternal breast milk. Approximately 10% of infants congenitally infected with CMV are symptomatic at birth. Common sites of involvement are liver, spleen, lungs, and central nervous system (CNS). Because specific antiviral therapy is available for treatment of these infants, rapid detection of CMV infection is necessary. Although most congenitally infected infants are asymptomatic at birth, approximately 10% to 15% of these will develop later problems such as hearing loss and other neurologic problems. In children and young adults, primary CMV infection can cause a mononucleosis-like illness.

**Diagnosis**

The detection of CMV in blood and tissues generally correlates with active disease, whereas detection of CMV in urine is not necessarily diagnostic of active CMV disease, even in immunocompromised patients. Quantitative PCR assays of CMV DNA in blood correlate with the likelihood of severe infection. Congenital CMV infection is established when CMV is isolated from the urine of neonates less than 3 weeks of age. CMV isolation from respiratory secretions of bone marrow transplant recipients is likely to be clinically significant because interstitial pneumonia is a complication of bone marrow transplantation. In AIDS patients, shedding of CMV in respiratory secretions does not always correlate with active infection. CMV serology is used to determine whether donors and/or recipients are latently infected with CMV. This has important implications for preventing subsequent infections. Diagnostic testing for CMV is summarized in Table 5–8.

**Parvovirus B19**

**Description**

Parvovirus B19 is a small single-stranded DNA virus that is transmitted by respiratory droplets. It is a common cause of infection in children in whom it causes a distinctive rash known as fifth disease. In adults, it often causes a significant arthropathy. An unusual feature of this virus is that it replicates in erythroid precursor cells and causes a temporary cessation of RBC production until the virus is cleared by the immune system. In normal hosts this has little, if any,

</table>
consequence, but in patients who have a chronic hemolytic anemia such as sickle cell disease or hereditary spherocytosis, the parvovirus B19 infection causes a transient aplastic crisis in which there is a profound drop in the hematocrit. Parvovirus B19 can cause a chronic anemia in immunocompromised patients who are unable to clear the virus. Intrauterine infection of the fetus can also cause a severe anemia that leads to congestive failure and hydrops fetalis.

Diagnosis
Acute parvovirus infection can be confirmed by demonstration of IgM antibodies or detection of viral DNA by PCR. During a transient aplastic crisis, the reticulocyte count decreases to <0.1% even as the hematocrit is declining.

ENDOCARDITIS: INFECTION OF THE HEART

Description
The clinical features of infectious endocarditis, a microbial infection of the valvular or nonvalvular endothelium of the heart, depend on the type of organism, location, and type of valve. Acute infective endocarditis can present with temperatures ≥103°F, shaking chills, rapid worsening of valve function, and a variety of septic embolic complications. Subacute bacterial endocarditis is characterized by a low-grade or absent fever (as a result of infection by low-virulence organisms), and a variety of nonspecific signs and symptoms such as anorexia, weight loss, and malaise. Acute bacterial endocarditis typically occurs on native heart valves. It is most often caused by virulent organisms such as *S. aureus*, beta-hemolytic streptococci, and less commonly by *S. lugdunensis*, *enterococci*, and *S. pneumoniae*. Subacute bacterial endocarditis is usually caused by viridans group streptococci, enterococci, and fastidious gram-negative rods from the oral cavity. Several difficult-to-grow organisms are associated with “culture-negative” endocarditis. Prosthetic valve endocarditis is often caused by coagulase-negative staphylococci but can also be caused by *S. aureus*, other skin flora, enteric gram-negative rods, and fungi.

There are a number of risk factors for endocarditis, particularly in the acute form. These include diabetes, alcoholism, intravenous drug use, malignancy, infections in other sites, and immunosuppression. Anatomic defects also predispose patients to the development of infectious endocarditis. Such defects include mitral valve prolapse, congenital or rheumatic heart disease, and calcific aortic stenosis. The worst prognosis among patients with valvular disease is associated with those who have aortic valve involvement. The mitral valve, however, is the most frequently involved. Most individuals with endocarditis are between 45 and 60 years of age.

Diagnosis
The clinical and laboratory features of acute and subacute bacterial endocarditis are different (Table 5–9). It should be noted, however, that patients can present with a syndrome of intermediate severity between acute and subacute endocarditis, usually as a result of infection by organisms of intermediate virulence, such as *Enterococcus* species, *Haemophilus* species, and the *Streptococcus bovis* group. Laboratory confirmation of infective endocarditis usually involves isolation of the same organism from multiple blood cultures. Organisms are more likely to be isolated from blood cultures in patients who have acute bacterial endocarditis because they have a high-grade persistent bacteremia. If 3 sets of blood cultures are obtained, the blood cultures are positive in more than 99% of patients who have not received antibiotics. At least 2 sets of blood cultures should be obtained by separate venipunctures at presentation. The erythrocyte sedimentation rate is a nonspecific test that is almost always elevated in cases of endocarditis, but it is useful for monitoring the response to therapy. It is not uncommon to obtain negative blood cultures in patients who meet the clinical and echocardiographic criteria for infectious endocarditis. Many of these “culture-negative” cases are due to prior antibiotic therapy. In the past, the “HACEK” group of fastidious oral gram-negative rods was linked to culture-negative endocarditis, but these organisms are readily detected by modern blood culture systems. More recently, interest has focused on *Coxiella burnetii*, *Bartonella* spp., *Tropheryma whippelii*, and *Brucella* spp. as potential causes of “culture-negative” endocarditis. These agents can be detected by a combination of serologic and molecular methods.
## INFECTIONS OF THE CENTRAL NERVOUS SYSTEM

### Overview

Many organisms can produce an infection within the CNS. The major sites of infection are the meninges and brain parenchyma. Most organisms gain access to the CNS by hematogenous spread or by direct extension from an adjacent site. Bacterial infections can cause acute meningitis or may lead to formation of a brain abscess. Viral infections can present as meningitis or encephalitis, but often both sites are involved and the infection is more appropriately described as meningoencephalitis. Both fungi and mycobacteria can cause chronic meningitis while several parasites can cause intracerebral mass lesions. Each of these syndromes is often associated with specific organisms, information that can be used to guide the diagnostic workup. Rational test ordering based on clinical presentation is particularly important in patients with CNS infections since diagnostic specimens are difficult to obtain and are often present in limited quantities. Table 5–10 provides information on organisms that are frequently described causes of meningitis and/or encephalitis.

### Acute Bacterial Meningitis

#### Description

Bacterial meningitis may present as a progressive illness over several days, or as a fulminant process that develops within hours. There is no single clinical sign that is pathognomonic of meningitis. Adolescents and adults typically present with combinations of fever, headache, nuchal rigidity, and other meningeal signs, and a decreased level of consciousness that can range from lethargy to coma; however, these findings are not present in all patients. Neonates and infants often present

CSF, cerebrospinal fluid; PCR, polymerase chain reaction.
with nonspecific signs such as irritability, while nausea and vomiting are frequent complaints in children. Confusion, often without fever, is a common presenting sign in the elderly.

In most cases, the bacteria responsible for meningitis are acquired through the upper respiratory tract and then invade the blood. From the blood, they can then seed the meninges. There are a variety of factors that increase the risk for development of meningitis. These include splenectomy, sickle cell disease, cerebrospinal fluid leak, fistula or shunt, recent neurosurgical procedure, and infection contiguous to the CNS.

The organisms responsible for acute bacterial meningitis are highly dependent on the age of the patient and the clinical setting. *S. agalactiae* (group B *Streptococcus* [GBS]), *E. coli*, or *Listeria monocytogenes* are responsible for most cases of neonatal and infant meningitis. *S. pneumoniae* and *N. meningitidis* are responsible for most cases of community-acquired bacterial meningitis in children and adults (widespread vaccination for *Haemophilus influenzae* type b has nearly eliminated this previous childhood scourge). Elderly patients are at increased risk of infection with *L. monocytogenes* and aerobic gram-negative rods. In contrast, staphylococci and gram-negative rods are major causes of CNS shunt infections and postneurosurgery nosocomial infections. Knowledge of these patterns is important when deciding on empiric antibiotic therapy.

### Diagnosis

Examination and culture of CSF is essential. There is usually a markedly elevated WBC count with a preponderance of neutrophils, elevated protein, and decreased glucose (relative to the blood level). Gram stain of CSF reveals the causative organism in 70% to 90% of cases of pneumococcal and meningococcal meningitis. The percentage is generally lower for other bacteria. Bacterial culture is essential in all cases because it has the greatest sensitivity and specificity. Patients who have rapidly progressive or severe disease frequently receive a dose of antibiotics before a CSF specimen can be collected. Although this may cause a false-negative culture, it should have little or no effect on the cell count and differential, protein, glucose, and Gram stain. Immunoassays that detect *S. pneumoniae* and *N. meningitidis* capsular antigens in CSF are useful in these patients with partially treated meningitis, but they are not more sensitive than a Gram stain.

### Acute Viral Meningitis

**Description**

Viral meningitis (often described as aseptic meningitis due to the absence of bacteria) presents with fever, headache, and meningeal signs. At least 75% of these infections are caused by members of the enterovirus family that includes the coxsackieviruses and echoviruses. Arboviruses (arthropod-borne viruses), HSV-2, HIV, and many other viruses can also cause this syndrome. Both enterovirus and arbovirus infections exhibit seasonal variation; most cases occur in the summer and early fall. Viral meningitis is usually a self-limited illness with a generally good prognosis. This is fortunate since there are currently no clinically useful antiviral drugs that are active against the enteroviruses and arboviruses. The clinical diagnosis of viral meningitis is often not clear-cut because there can be parenchymal involvement leading to varying degrees of encephalitis (see below). In addition, several other conditions can cause a similar clinical syndrome. These include partially treated bacterial meningitis, neoplastic diseases that have spread to the meninges, and immune-mediated diseases. It is important to identify these conditions because each of them is treatable and requires specific therapy.

Acute bacterial meningitis must be differentiated from viral and fungal meningitis. There is a significant difference in the CSF findings between viral and bacterial meningitis (Table 5–11).

**Diagnosis**

CSF analysis usually reveals an elevated WBC count with a preponderance of mononuclear cells, elevated protein, and a normal glucose. Identification of the causative agent is best achieved through the use of specific nucleic acid amplification tests or immunoassays; routine viral culture has a relatively poor yield in most cases. Many clinical or reference laboratories offer RT-PCR assays for enteroviruses, HSV, and West Nile virus. Immunoassays for detection of IgM and IgG are used to detect other viruses. Bacterial culture and cytopathology examination may be indicated if the diagnosis is unclear.

bThe percentage of neutrophils can be elevated during early stages of infection.

**Chronic Meningitis**

**Description**

Patients suffering from chronic meningitis usually present with a variety of signs including low-grade fever, headache, lethargy, confusion, nausea, vomiting, and stiff neck that develop over a period of 1 to 4 weeks. Fungi and mycobacteria are responsible for many cases of chronic meningitis. The encapsulated yeast, *C. neoformans*, is 1 of the most common causes, particularly in patients with depressed cell-mediated immunity due to HIV infection or immunosuppressive therapy. *C. neoformans* is acquired by inhalation that usually causes an asymptomatic pulmonary infection. These organisms then spread to the CNS by the hematogenous route. *C. gattii*, previously classified as a subspecies of *C. neoformans*, often causes meningitis in patients who are not infected with HIV. *Coccidioides immitis* and *C. posadasii*, dimorphic fungi that are prevalent in the southwestern United States, are also acquired by inhalation and have a predilection for infecting the meninges and CNS. Immunosuppressed patients who harbor *Mycobacterium tuberculosis* are at increased risk of CNS tuberculosis (TB). Neoplastic and immune-mediated diseases can also cause chronic meningeal symptoms; it is important to distinguish between these conditions and infection.

**Diagnosis**

The diagnosis of chronic meningitis requires evaluation of the CSF. Typically there are an increased number of mononuclear cells, mildly elevated protein, and normal glucose (except in TB). Immunoassays for *C. neoformans* capsular polysaccharide can be performed in less than an hour, have a very high sensitivity and specificity, and are superior to visual examination of India ink preparations (the antigen test does not distinguish between *C. neoformans* and *C. gattii*). Fungal culture should also be performed. If the patient is at increased risk of disseminated TB (ie, purified protein derivative [PPD]-positive or a history of pulmonary TB), then the CSF should be tested for mycobacteria. AFB smears are quite insensitive. PCR of CSF can provide early confirmation of *M. tuberculosis* infection in many cases. However, culture should still be performed to obtain an isolate for susceptibility testing.

**Encephalitis**

**Description**

Viral encephalitis is an infection of the brain parenchyma that can produce permanent neurologic damage or death in persons of all ages. A higher incidence of viral encephalitis is found in young children, the elderly, and persons with impaired immunity. For some viruses, there is a seasonal variation for infection. Most of the viruses that produce encephalitis enter the CNS via the hematogenous route. In its mildest form, viral encephalitis can present with fever and headache, and in its most severe form as an acute fulminating disorder with seizures and death. Prominent clinical findings include altered level of consciousness, altered mental status, headache, seizures, and other signs of neurologic dysfunction. The most important cause of sporadic encephalitis is HSV-1 that often causes permanent neurologic damage or death. Fortunately, there is effective
Viral encephalitis is an infection of the brain parenchyma that can produce permanent neurologic damage or death in persons of all ages. The most important cause of sporadic encephalitis is HSV-1 that often causes permanent neurologic damage or death.

Antiviral therapy for HSV encephalitis that can prevent most of these complications if given early in the infection. Arboviruses transmitted by mosquitoes are responsible for periodic epidemics of encephalitis. A dramatic example of this phenomenon was the appearance of West Nile virus in the eastern United States in the summer of 1999 and its subsequent spread across the country during the next 4 years. Arboviral encephalitis is usually a self-limited infection. Most patients recover, but a significant number have persistent neurologic symptoms. Amebas such as Naegleria should also be considered in the differential diagnosis of encephalitis since they require specific therapy.

**Diagnosis**

The diagnosis of viral encephalitis includes evaluation of CSF. In patients with viral encephalitis, there is a predominantly lymphocytic pleocytosis, with a slight to moderate elevation of CSF protein, and no change in glucose content from normal. However, there are variations, depending on the virus that produces the encephalitis. Some of the agents can produce CSF findings that mimic those of bacterial meningitis (eg, pleocytosis with an increased number of neutrophils), particularly during the early stages of infection. The diagnosis of HSV encephalitis should be confirmed with a PCR assay of CSF that detects HSV DNA. This test is very sensitive and specific. Because of the severity of HSV infections and the availability of effective treatment, it should be performed on any patient with suspected encephalitis. Viral culture of CSF is insensitive and should not be routinely performed. Encephalitis caused by other viruses is often diagnosed by detection of viral nucleic acid or virus-specific IgM and IgG in serum or CSF.

Table 5–10 presents the laboratory evaluation for meningitis and encephalitis by disease and/or organism. Organisms not listed in the table also may cause CNS infections. Chapter 2 provides descriptions of many of the tests mentioned in the table.

**Brain Abscess**

**Description**

A brain abscess is a focal lesion and therefore presents differently from meningitis and encephalitis. The most common clinical presentation is persistent, worsening headache. More than half of patients will have focal neurologic deficits, but only half have fever. Bacterial abscesses can result from hematogenous dissemination or extension from an adjacent site. The most common organisms are viridans group streptococci, Haemophilus spp., and anaerobic gram-negative rods. If the patient is immunosuppressed, then the abscess could be caused by Aspergillus and other fungi, Nocardia spp. and Mycobacterium spp., and Toxoplasma gondii. Neurocysticercosis, a mass lesion that results from infection with the pork tapeworm Taenia solium, often presents as new-onset seizures in an adult.

**Diagnosis**

Unlike other CNS infections, examination of CSF is unlikely to yield useful information and even performing a lumbar puncture may be contraindicated. The initial diagnosis is usually based on CT and MRI findings. Identification of the causative agent is important for guiding therapy. This usually requires stereotactic biopsy of the abscess to obtain material for microscopic examination and culture. Serologic assays performed on serum may be helpful in the diagnosis of Toxoplasma infections and neurocysticercosis.

**BONE INFECTIONS/OSTEOMYELITIS**

**Description**

Osteomyelitis is an infection of the bone characterized by progressive, inflammatory destruction of the bone tissue. It can be classified by the route of infection (hematogenous, contiguous spread, direct traumatic, or surgical inoculation), the site of infection, the type of patient, or duration of infection (acute or chronic). Hematogenous osteomyelitis is most common in prepubertal children, where it usually involves the long bones, and older adults where it usually involves the vertebrae. Less common sites of osteomyelitis include the sternoclavicular and sacroiliac joints, and symphysis pubis. Children with acute osteomyelitis appear ill with fever, chills, localized pain, and leukocytosis. In contrast, adults with vertebral osteomyelitis often have a subacute course with
CHAPTER 5  Infectious Diseases

Infectious Diseases

slowly worsening back pain and little or no fever or leukocytosis. Hematogenous osteomyelitis is usually caused by a single organism. *S. aureus* accounts for half of cases. Other frequently encountered organisms are streptococci and enterobacteriaceae in neonates, gram-negative rods in the elderly, *Salmonella* spp. in patients with sickle cell disease, *P. aeruginosa* in intravenous drug users, and *Candida* spp. in patients with intravascular catheters. TB and brucellosis can cause vertebral osteomyelitis in patients who have been exposed to these organisms.

Osteomyelitis caused by a contiguous focus of infection often results from an injury associated with an open fracture or following surgery for reconstruction of bone. It is also common in patients with poorly controlled diabetes mellitus due to peripheral neuropathy and vascular insufficiency. This form of osteomyelitis is found almost exclusively in the foot and starts insidiously in areas of traumatized skin. The infection of the skin may be easily overlooked as the organism makes its way to the bones in the toes, metatarsal heads, and tarsal bones. Unlike hematogenous osteomyelitis, these contiguous focus infections are usually polymicrobial involving combinations of staphylococci, streptococci, enterococci, and gram-negative rods. Additional classes of organisms may be present in the wound if the injury site was contaminated with soil. With between 500,000 and 1,000,000 hip replacements per year worldwide, infections associated with prosthetic joints are also common (see the section “Infections of the Joints”).

**Diagnosis**

Imaging techniques can be used to detect osteomyelitis in the early phase and reveal the extent of damage to bones and joints. Definitive diagnosis requires biopsy and culture of the infected tissue in most cases. This permits an accurate identification of the organisms responsible for the osteomyelitis. In some situations, the organisms suspected of causing osteomyelitis may be identified from the culture of synovial fluid, blood, or biopsy of contiguous lesions. Microbiologic culture of blood or contiguous tissue does not definitively identify the organism in the bone, but it may provide a strong indication of the organisms responsible for the osteomyelitis.

Table 5–12 lists the organisms most likely to cause osteomyelitis and identifies the populations at risk for infection by the named organisms.

**INFECTIONS OF THE JOINTS**

**Description**

Acute pain and swelling in the joint can be produced by infectious agents, crystals of monosodium urate or other compounds, and a variety of less common causes. Because some organisms

Infectious Diseases

can destroy cartilage in a matter of days, the diagnosis of infectious arthritis must be made quickly. Organisms can seed the joint through the hematogenous route (via intravenous drug abuse, indwelling catheters, endocarditis), through direct inoculation from intra-articular injections or arthroscopy, or from a contiguous site of infection, especially the bones and bursae. Septic arthritis can resemble a variety of noninfectious processes, but an acutely inflamed joint should be considered septic until proved otherwise. Septic arthritis is most often monoarticular with polyarticular involvement in less than 20% of the cases.

Diagnosis

The mainstays of the laboratory investigation for a joint infection are synovial fluid Gram stain and culture to identify infecting organisms, and polarized microscopy of the synovial fluid to identify crystals in crystal-induced arthritis.

CHAPTER 5  Infectious Diseases

INFECTIONS OF THE SKIN AND ADJACENT SOFT TISSUE

Overview

Many different organisms can produce infections of the skin and soft tissue. Clinical manifestations and severity vary widely and include aggressive, fast-moving infections such as necrotizing fasciitis, abscesses that require incision and drainage, chronic superficial fungal infections, and rashes that can be caused by local or systemic viral infections. A brief description of infections associated with particular organisms is provided in Table 5–14. The diagnostic information to identify infecting organisms is also included in the table. Lyme disease and Bartonella infections are discussed in Tables 5–15 and 5–16. A number of other infectious diseases, such as syphilis and herpes simplex infections, also have skin manifestations and are more fully described elsewhere in this chapter.

Acute Bacterial Infections

Abscesses, infected wounds, and cellulitis are common acute infections of the skin. The most common organisms are S. aureus, beta-hemolytic streptococci (groups A and B), other streptococci and staphylococci, and several gram-negative rods. Certain underlying conditions, such as diabetes and peripheral vascular disease, predispose to polymicrobial infections involving gram-positive cocci and gram-negative rods.

CHAPTER 5  Infectious Diseases

Clostridial myonecrosis (gas gangrene)

Rapidly progressive infection characterized by muscle necrosis and systemic toxicity caused by potent clostridial exotoxins

Wounds associated with trauma and open fractures such as gunshot wounds; intestinal and biliary tract surgery

C. perfringens accounts for 80% of cases; other species include C. septicum, C. novyi, and C. sordelli; the toxins released by these organisms are responsible for much of the morbidity and mortality associated with these infections

Sudden onset of severe pain at the site of a wound with rapid progression to localized tense edema and pallor; crepitance is a late finding and is neither a sensitive nor a specific feature; as the lesion progresses, the skin progresses to magenta or brown discoloration with brown serosanguinous discharge and “mousey” odor

Surgical exploration critical in demonstrating devitalized muscle tissue; CT scan shows gas in the muscle and in fascial planes with soft tissue swelling; Gram stain of exudate shows typical gram-positive or gram-variable rods with spores and lysed or absent neutrophils; with C. perfringens, organism shows typical boxcar appearance without spores on Gram stain, “double-zone hemolysis” on anaerobic blood plate, and lecithinase activity (alpha-toxin); elevated CK, LDH, and myoglobin due to myonecrosis

CT, computed tomography; LDH, lactate dehydrogenase.

Cat/dog and human bite wounds are commonly infected with the above organisms, but they are also associated with specific organisms (Pasteurella multocida and Eikenella corrodens, respectively).

Necrotizing fasciitis (usually caused by S. pyogenes) and clostridial myonecrosis (also known as gas gangrene) are uncommon, but they are life-threatening infections that require prompt surgical and medical intervention. Traumatic gas gangrene is usually caused by contamination of wounds by Clostridium perfringens (an anaerobic spore-forming gram-positive rod). Spontaneous gas gangrene is usually caused by C. septicum, often in patients with underlying gastrointestinal malignancies or neutropenia.

**Lyme Disease**

**Description**

The causative agent of Lyme disease is Borrelia burgdorferi, which is spread by the bite of a tick of the genus Ixodes. Lyme disease is the most common vector-borne infection in North America and
in Europe. It tends to go unnoticed by many patients because the associated influenza-like symp-
toms are not specific for the disease. Within days to weeks of infection, a distinctive skin rash,
known as erythema migrans, appears. It is important to treat the patient at the time that this rash
appears to prevent subsequent potential neurologic, cardiac, or musculoskeletal complications.

**Diagnosis**

Unlike many infections, this laboratory diagnosis is rarely based on culture of *B. burgdorferi*. This
is because there are few organisms in clinical specimens, and these organisms require specialized
media for growth with prolonged incubation. Therefore, the diagnosis rests upon a characteristic
clinical picture supported by positive serologic tests consistent with the infection. In patients who
present with erythema migrans, the diagnosis is straightforward. However, for many patients with
less specific symptoms and equivocal serologic test results, it is difficult to make a definitive diag-
nosis. Serologic testing for Lyme disease is a 2-step process involving a screening enzyme-linked
immunoassay (ELISA), followed by a confirmatory immunoblot (see Chapter 2 for a description

**TABLE 5–15 Laboratory Evaluation for Lyme Disease**

</tr>
</tbody>
</table>

CNS, central nervous system; PCR, polymerase chain reaction.
of these assays). There are several important issues regarding the serologic assays to detect Lyme disease:

- The serologic tests are not entirely specific for Lyme disease.
- Serum samples collected in the early stage of the disease may contain no antibodies to the organism because there is little or no antibody production in many patients until 3 to 4 weeks after the onset of the illness.
- The immune response is variable, and treatment with antibiotics can reduce the magnitude of the response.

Cross-reactivity between the antigens from *B. burgdorferi* and antigens from other organisms may occur. For example, false-positive serologic reactions for Lyme disease have been reported in patients with RMSF, leptospirosis, and syphilis. False-positive reactions can also occur in some patients with autoimmune diseases.

PCR-based assays for detection of *B. burgdorferi* DNA may be useful for testing joint fluid or CSF. Only properly validated assays should be used since in a low-prevalence population (ie, patients with nonspecific symptoms and no history of a tick bite) the positive predictive value can be very low. A summary of the different assays currently available for diagnosis of Lyme disease is provided in Table 5–15.

### Cat-scratch Disease and Bacillary Angiomatosis

#### Descriptions

Several organisms of the genus *Bartonella* were found to be associated with human disease in the 1990s when they were identified as the etiologic agents in cat-scratch disease and bacillary angiomatosis. Most cases of cat-scratch disease are caused by *B. henselae* (other *Bartonella* spp. and *Afi pia felis* may account for a small percentage of these cases). Initially a papule or pustule forms at the site of the scratch, but most individuals seek medical attention several weeks later because of the development of a regional lymphadenopathy (mainly in the neck or upper extremity). In most cases, it resolves spontaneously, although in rare cases severe complications can occur, including encephalitis, conjunctivitis, and neuroretinitis. Bacillary angiomatosis is a disorder in which there are distinctive and potentially lethal vascular proliferative responses in the skin, the bones, and other organs. Bacillary angiomatosis is most commonly diagnosed in individuals infected with HIV.

#### Diagnosis

A further description of cat-scratch disease and bacillary angiomatosis and recommendations for their diagnosis are included in Table 5–16. Serologic tests and PCR-based tests may be useful to support the histopathologic findings from lymph node biopsies in cat-scratch disease and from skin biopsies in bacillary angiomatosis. *Bartonella* spp. are difficult to culture.

### Fungal Infections

Fungal infections of the skin can be characterized as superficial, cutaneous, and subcutaneous. Infections caused by fungi such as *Malassezia* spp. are limited to the superficial layers of the skin and can result in patchy alteration of pigmentation. The more invasive cutaneous infections caused by dermatophytes and subcutaneous infections are discussed in the following sections.

#### Descriptions

The dermatomycoses (also known as ringworm) are skin infections caused by dermatophytes. These organisms are closely related fungi that invade keratinous tissues such as skin, hair, and the fur of animals. The dermatophytes are classified into 3 genera, *Epidermophyton*, *Microsporum*, and *Trichophyton*. Dermatophyte infections are named according to the anatomic location (in Latin) for the body site, following the word “tinea.” For example, tinea pedis is a dermatophyte infection of the foot. The diagnosis of a dermatophyte infection is made by microscopic examination of a scraping of the lesion and by culturing the specimen...
on selective agar that inhibits the growth of commensal bacteria and other fungi. When organisms are successfully grown in culture, they are identified to the species level by colony and microscopic morphology.

Sporotrichosis is a chronic infection characterized by nodular lesions in cutaneous and subcutaneous tissues and adjacent lymphatics. This infection is caused by *Sporothrix schenckii*, a dimorphic fungus that is typically introduced by traumatic implantation into the skin (e.g., during gardening). Sporotrichosis commonly displays a lymphocutaneous pattern as it tracks up the lymphatic system in the hand and arm. Rare manifestations include pulmonary and disseminated infections. Histologic examination of a specimen will often reveal granulomatous inflammation, but organisms are rarely seen. Therefore, diagnosis usually depends on culturing the specimen to permit microbiologic isolation of the *S. schenckii* organisms.

Mycetoma is a chronic infectious disease that involves cutaneous and subcutaneous tissues, fascia, and bone, and remains localized. It is characterized by draining sinuses, with aggregates of the etiologic agent in the pus draining from the sinuses. The fungi that produce the mycetomata are associated with woody plants and soil. The organisms are usually introduced by traumatic inoculation into the skin. A tumor-like deforming disease can develop during subsequent years if untreated. Dozens of fungal organisms have been documented as causes of mycetoma. In the United States, the most common agent is *Pseudoallescheria boydii*. The asexual form of this organism is known as *Scedosporium apiospermum*. Other fungi predominate in tropical and subtropical areas. The fungal elements are most often found in the center of a suppurative and granulomatous lesion that develops in a deep site and extends out to the skin for drainage. Draining sinuses appear in essentially all patients within 1 year of the initial trauma. Identification of the causative agent is made by fungal smear and culture of the material draining from the sinus tracts. Clinically similar infections are caused by filamentous gram-positive bacteria in the genus *Nocardia*.

It is important to identify the infecting agent because the therapy for fungi is very different from that used for bacteria.

Chromomycosis is a subcutaneous infection by organisms originating in the soil, with only rare cases of dissemination. It is most often seen in tropical or subtropical environments and is rare in the United States. The lesions typically appear on the lower extremities. They are pink, scaly papules that expand to form a superficial nodule, and their presence suggests the diagnosis. Examination of the lesions microscopically in potassium hydroxide (KOH) or calcofluor white preparations can be diagnostic. Without therapy, which is usually surgical, the scaly papules grow to form nodules with a verrucous and friable surface.

**Diagnosis**

A further description of the infections and the tests used to identify the associated organisms are included in Table 5–17.

**Viral Infections With Prominent Skin Manifestations**

**Overview**

Viral infections can cause a variety of macular, papular, or vesicular rashes. Many of these typically occur in the pediatric age range and may be associated with systemic signs and symptoms. Enteroviruses and parvovirus B19 are discussed in other sections.

**Varicella Zoster Viral Infection**

**Description**

Primary infection with VZV causes chickenpox, a vesicular rash that occurs predominantly on the trunk, scalp, and face. This disease is usually self-limited, with the symptoms resolving after 7 days. Varicella can also produce pneumonia, with pulmonary symptoms manifested approximately 4 days after the varicella rash. After primary infection, the virus enters the latent phase and remains in sensory ganglia. On reactivation, which occurs in a minority of adults, it produces herpes zoster, a vesicular rash that occurs along a dermatome distribution. The incidence of varicella has been declining since the introduction of a live virus vaccine.

AFB, acid-fast bacilli; KOH, potassium hydroxide.
Diagnosis

Chickenpox and herpes zoster are diagnosed clinically in most cases because of the characteristic presentation of the diseases. Laboratory tests for the VZV virus, although they represent the gold standard for diagnosis, are typically unnecessary. Cutaneous lesions may be evaluated for the presence of VZV by direct immunofluorescence. Serologic testing is often important to determine whether an individual has ever been infected with VZV. Assays for VZV infection are summarized in Table 5–18.

Measles (Rubeola) and Rubella

Description

Measles (or rubeola) is a highly contagious childhood disease characterized primarily by fever and a rash. The primary portal of entry for the rubeola virus is the upper respiratory tract. Approximately 14 days after exposure to the rubeola virus, a characteristic measles rash appears, and within 1 to 2 additional days there is a measurable amount of antibody to rubeola virus in the bloodstream. The leading cause of death in patients with measles is secondary bacterial pneumonia. Rubella, also known as German measles, is most often a mild illness in children and young adults. It is widely recognized as a dangerous infection in early pregnancy when an infection of the fetus can cause congenital abnormalities. Rubella is characterized by a rash and an enlargement of lymph nodes. Like the rubeola virus, the portal of entry of rubella virus is most often the respiratory tract. The availability of vaccines against measles and rubella has greatly decreased the incidence of these infections in the United States.

Diagnosis

The laboratory diagnosis of measles or rubella can be important for epidemiologic surveillance purposes and to limit its transmission to susceptible individuals. The laboratory diagnosis is usually based on detecting virus-specific IgM in serum or isolation of the virus from urine or respiratory specimens.

Within 24 to 48 hours of the development of a rash, antibodies to rubella become detectable. Primary infection stimulates production of antibodies that confer lifelong immunity. It is for this reason that the presence of antibodies to rubella is desirable before initiating pregnancy. The antibodies can be demonstrated in a serologic test that indicates exposure to the rubella virus. Serologic testing is an important component of the evaluation of a pregnant woman with the clinical signs and symptoms of rubella. Table 5–19 summarizes the laboratory evaluation for rubeola and rubella.

Rubeola and rubella infections are often confused because of the similarity in their names and similar clinical manifestations. Measles (or rubeola) is a highly contagious childhood disease characterized primarily by fever and a rash. Rubella, also known as German measles, is most often a mild illness in children and young adults.
CHAPTER 5  Infectious Diseases

EYE INFECTIONS

Description and Diagnosis
Infectious agents play a prominent role in many diseases of the eye. Table 5–20 describes the infections of the eye according to anatomic site of infection within the eye. Many organisms that produce eye infections are described in detail in other sections of this chapter. The microbiologic isolation and tests for identification of the organisms listed in Table 5–20 as causative for disease are presented in other sections of this chapter.

INFECTIONS OF THE LARYNX, PHARYNX, MOUTH, EAR, ORBIT, AND SINUSES

Description and Diagnosis

Table 5–21 describes the infections of the pharynx, larynx, mouth, ear, orbit, and sinuses. Because there are such a large number of organisms that produce these infections, a brief description of the infections and their associated organisms is presented in Table 5–21. For similar reasons, the diagnostic studies useful in identifying the disease and its causative organisms are also provided in the table.

**INFECTIONS OF THE LUNG AND PLEURAE**

**Overview**

Many categories of organisms can cause pneumonia and other types of pulmonary infections. It is very important to consider the clinical setting when evaluating and managing a patient with pneumonia because the types of organisms that are responsible depend on whether or not specific risk factors are present.

Community-acquired pneumonia is commonly caused by *S. pneumoniae*, *Mycoplasma pneumoniae*, respiratory viruses, *H. influenzae*, and *Legionella* spp. In contrast, hospital-associated and ventilator infections are likely to be caused by multidrug-resistant organisms including *K. pneumoniae*, *P. aeruginosa*, *Acinetobacter baumannii* complex, and MRSA. *P. aeruginosa*, *Burkholderia cepacia*, and MRSA are also important causes of lung infections in patients with cystic fibrosis. In recent years there has been an increase in the number of *Bordetella pertussis* infections that has been attributed to waning immunity following the introduction of acellular pertussis vaccines.

Travel and/or exposure history can be an important clue in patients with persistent pulmonary signs and symptoms, as they may have TB or dimorphic fungal infections (described below). Patients with depressed cell-mediated immunity (eg, transplant recipients or HIV infection) are at increased risk of *Pneumocystis* and CMV infections. Patients who have prolonged neutropenia from chemotherapy, for example, are at increased risk of invasive infections caused by *Aspergillus* spp. and other fungi.

Table 5–22 describes the infections of the lung and pleurae. The many different lung infections are grouped into bacterial, fungal, parasitic, and viral diseases. There are 2 major challenges...

<td>Serologic tests not useful</td>
</tr>
<tr>
<td><em>Chlamydia pneumoniae</em></td>
<td>Pharyngitis, hoarseness, fever, mild pneumonitis; atypical pneumonia, especially in the elderly</td>
<td>CXR usually reveals single subsegmental lesion; pleural effusion may be evident</td>
<td><em>Chlamydia</em> culture possible but requires specialized cell lines; PCR assays for direct detection are commercially available</td>
<td>IgM and IgG serologic tests for antibody to the organism may be useful for diagnosis; PCR assays for direct detection are commercially available</td>
</tr>
<tr>
<td><em>Coxiella burnetii</em> (Q fever)</td>
<td>Causes atypical pneumonia with fever, severe headache, chills, sweats, myalgia; associated with exposure to livestock</td>
<td>CXR often shows multiple rounded opacities</td>
<td>Culture and PCR only performed in specialized or reference laboratories</td>
<td>IgM and IgG serologic tests for antibody to the organism most useful for initial diagnosis; normal WBC count; elevated smooth muscle autoantibodies often present</td>
</tr>
<tr>
<td><em>Klebsiella pneumoniae</em></td>
<td>Bronchitis, bronchopneumonia, or lobar pneumonia; “currant jelly” sputum; frequent complications such as abscess and empyema</td>
<td>CXR may reveal pattern of pneumonia and identify complications, if they arise</td>
<td>Sputum from lower respiratory tract for Gram stain and culture</td>
<td></td>
</tr>
<tr>
<td><em>Haemophilus influenzae</em> (nontypable)</td>
<td>Pneumonia with fever, productive cough; often exacerbates chronic bronchitis</td>
<td>CXR may show interstitial or bronchopneumonia, or pneumonia with consolidation</td>
<td>Sputum or other lower respiratory tract specimen for Gram stain and culture</td>
<td></td>
</tr>
<tr>
<td><em>Legionella pneumophila</em> (also see the section “Legionella Infections”)</td>
<td>Atypical pneumonia with slightly productive cough, fever, and chest pain; diarrhea often present</td>
<td>CXR typically shows alveolar infiltrates; pleural effusions common</td>
<td>Respiratory specimens cultured on selective media; urinary antigen test is rapid and sensitive for serogroup 1</td>
<td>Hyponatremia often present; PCR and serologic tests may be useful for diagnosis</td>
</tr>
<tr>
<td><em>Mycobacterium avium-intracellulare complex</em> (another nontuberculous mycobacterium)</td>
<td>In the non-HIV-infected patient, pulmonary disease with productive cough, fever, weight loss, and occasionally hemoptysis</td>
<td>CXR mimics reactivation tuberculosis with cavitation</td>
<td>Sputum from lower respiratory tract specimen for acid-fast stain and culture (must distinguish active disease from colonization)</td>
<td>In HIV-infected population, must distinguish atypical mycobacteria from <em>Mycobacterium tuberculosis</em> infection</td>
</tr>
<tr>
<td><em>M. tuberculosis</em> (see the section “Tuberculosis”)</td>
<td></td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td><em>Mycoplasma pneumoniae</em></td>
<td>Often causes an upper respiratory tract infection with fever, malaise, headache, and nonproductive cough; may cause atypical pneumonia</td>
<td>CXR may show extensive infiltrates, out of proportion with symptoms</td>
<td>Difficult to diagnose by microbiologic culture; cultures require 1-4 weeks for growth with special media; not detected by Gram stain</td>
<td>IgM and IgG tests are useful (may require acute and convalescent serum); can also be used for diagnosis</td>
</tr>
<tr>
<td><em>Pseudomonas aeruginosa</em></td>
<td>Causes pneumonia in elderly, hospitalized, and cystic fibrosis patients; may be fulminant with chills, fever, dyspnea, excessive purulent sputum, and cyanosis</td>
<td>CXR may reveal diffuse bronchopneumonia; in bacteremic pneumonia, alveolar and interstitial infiltrates with cavitation may be seen</td>
<td>Sputum from lower respiratory tract for Gram stain and culture; blood cultures may be positive</td>
<td>Mucoïd isolates often obtained from cystic fibrosis patients</td>
</tr>
</tbody>

<td>Pneumonia with fever, purulent sputum</td>
<td>CXR shows infiltrates, consolidation, abscesses, pleural effusions, and/or loculations</td>
<td>Sputum from lower respiratory tract for Gram stain and culture; pleural fluid or empyema if present should be cultured; blood cultures may be positive</td>
<td>Empyema is a frequent complication that requires drainage; pleural fluid very purulent with many neutrophils</td>
</tr>
<tr>
<td><strong>Streptococcus agalactiae</strong> (group B streptococci)</td>
<td>Causes pneumonia in neonates and elderly; fever present; apnea, tachypnea, grunting, and cyanosis in neonates</td>
<td>CXR in neonates may show pulmonary infiltrates, often similar to hyaline membrane disease</td>
<td>Sputum from lower respiratory tract for Gram stain and culture</td>
<td>Pregnant carrier females may be screened by culture of vaginal and rectal swab specimens; nucleic acid amplification tests are an alternative</td>
</tr>
<tr>
<td><strong>Streptococcus pneumoniae</strong></td>
<td>Productive cough with rust-tinged sputum, fever, shaking chills, and pleuritic chest pain</td>
<td>CXR may show subsegmental infiltrations; segmental or lobar consolidation may be present</td>
<td>Sputum from lower respiratory tract for Gram stain and culture; blood cultures may yield organisms</td>
<td>Peripheral blood leukocytosis frequent; empyema is an uncommon complication</td>
</tr>
<tr>
<td><strong>Streptococcus pyogenes</strong> (group A streptococci)</td>
<td>Abrupt onset of pneumonia with fever, chills, dyspnea, pleurisy, and blood-tinged sputum</td>
<td>CXR reveals bronchopneumonia with consolidation</td>
<td>Sputum from lower respiratory tract for Gram stain and culture; blood cultures may be positive</td>
<td>Empyema is a frequent complication</td>
</tr>
</tbody>
</table>

- **Fungal infections** (see the section “Dimorphic Fungi and Other Fungal Infections”)
- **Pneumocystis** (see the section “Pneumocystis jirovecii Pneumonia”)

#### Viral infections

- **Adenovirus**
  - Pharyngitis or tracheitis with cough, fever, sore throat, and rhinorrhea; interstitial pneumonia may develop; diarhea also may be present
  - Adenoviral eosinophilic inclusions may be visible in lung biopsies if they are obtained
  - Adenoviral culture from respiratory specimens; rapid viral antigen detection by DFA can be useful; nucleic acid amplification is useful
  - With serologic testing, a 4-fold rise in titer is consistent with new infection

- **Cytomegalovirus (CMV)**
  - Interstitial pneumonitis with nonproductive cough, fever, dyspnea, and hypoxia
  - CXR shows interstitial pneumonia; nodules or cavities may be seen; lung biopsies reveal CMV inclusions (“owl’s eye” cells)
  - Viral cultures from respiratory specimens (bronchoalveolar lavage fluid or tissue); can also use PCR
  - Quantitative PCR assays using blood are preferred for diagnosis of disseminated disease

- **Hantavirus**
  - Fever, severe myalgias, headache, tachypnea, and shortness of breath; rapidly progressive to hypotension, respiratory failure, and shock
  - CXR shows rapid progression to bilateral interstitial edema and diffuse alveolar disease; pleural effusions often present
  - Immunohistochemistry or PCR using blood or lung biopsy may confirm infection
  - IgM serologic tests by capture enzyme immunoassay or Western blot are diagnostic methods of choice

- **Influenza A or B virus**
  - Fever, chills, myalgias, headaches, dry cough; primary viral pneumonia may occur
  - CXR may show bilateral infiltrates
  - Nucleic acid amplification (RT-PCR) performed on nasopharyngeal specimens is most sensitive method; DFA plus viral culture is also useful
  - Rapid antigen detection tests have poor sensitivity, often less than 50%

- **Human metapneumovirus**
  - Bronchiolitis and pneumonia similar to respiratory syncytial virus infections
  - CXR may show interstitial infiltrates or hyperinflation
  - Nucleic acid amplification (RT-PCR) performed on nasopharyngeal specimens is most sensitive method; DFA test is less sensitive; grows poorly in culture

*Continued next page—*
in the laboratory diagnosis of pulmonary infections. First, it can be difficult to obtain respiratory specimens that are not contaminated with oropharyngeal flora. This is particularly true of expectorated sputum. It is 1 of the reasons why this type of specimen is routinely screened microscopically for the presence of squamous epithelial cells to determine whether it is a true lower respiratory specimen. The other problem is that there is no single test that detects all of the potential respiratory pathogens. While routine Gram stain and sputum culture readily detects *S. pneumoniae*, common gram-negative rods, and *S. aureus*, separate cultures and/or test methods are required to detect *Legionella*, mycobacteria, fungi, respiratory viruses, CMV, and *Pneumocystis*. These are discussed in more detail in the following sections.

**Tuberculosis**

**Description**

TB is a major cause of morbidity and mortality around the world and remains a major challenge for public health officials. Approximately one third of the world’s population is estimated to be infected with the causative agent, *M. tuberculosis*. Early identification of patients with active pulmonary TB is crucial for preventing transmission of this serious infection to other patients and to health care workers.
Infectious Diseases of newly diagnosed infections with TB were limited to the lung, with 15% involving nonpulmonary sites or both pulmonary and nonpulmonary sites. With advanced HIV infection, less than half the cases are limited to pulmonary involvement. Extrapulmonary TB commonly involves the lymph nodes, pleura, genitourinary tract, bones and joints, meninges, peritoneum, and pericardium.

Early identification of patients with active pulmonary TB is crucial for preventing transmission of this serious infection to other patients and health care workers. Treatment of active TB caused by sensitive strains requires combination therapy for 6 months. Multidrug-resistant and extremely resistant *M. tuberculosis* (MDR-TB and XDR-TB, respectively) are more difficult to treat and have a poorer outcome.

**Diagnosis**

There are 2 categories of laboratory tests for TB: those that detect latent infection and those that detect active disease. Skin testing with PPD detects previous exposure to *M. tuberculosis*. A delayed-type hypersensitivity response to the *M. tuberculosis* antigens (mediated by T cells) leads to induration at the site of injection. One problem with the PPD test is that individuals who have been vaccinated with bacille Calmette–Guerin (BCG) can also have a positive reaction. BCG is derived from *M. bovis*, a member of the *M. tuberculosis* complex, and is widely used outside the United States. Recent advances in immunology and genomics have led to the development of alternatives to the PPD test, such as interferon-gamma release assays (IGRAs). Peripheral blood or purified mononuclear cells are incubated with antigenic peptides that are unique to *M. tuberculosis* (ie, they are not present in BCG) and then an immunoassay is performed to measure production of interferon-gamma. The IGRAs are at least as sensitive as the PPD and are more specific since BCG vaccination does not produce a false-positive result.

The diagnosis of secondary TB depends on detection of *M. tuberculosis* in clinical samples. This testing is particularly important since the PPD and IGRAs can be negative in patients with active TB. Acid-fast staining of sputum specimens (using either a fuchsin [red] stain or a fluorescent stain) enables visualization of the mycobacteria in ~70% of cases of pulmonary TB. Detection of mycobacteria in sputum using an AFB stain provides only presumptive evidence of pulmonary TB in the presence of characteristic radiologic findings. The presence of *M. tuberculosis* must be confirmed by culturing the organism in liquid and/or solid media or by using NAATs. Modern automated liquid culture systems routinely detect growth of *M. tuberculosis* in 1 to 2 weeks versus 4 to 6 weeks with traditional culture on solid media. These systems also make it possible to perform rapid susceptibility testing in liquid culture for first-line antituberculous drugs. The NAATs make possible same-day confirmation of smear-positive specimens, which contain relatively large numbers of organisms. Culture remains the gold standard for detecting *M. tuberculosis* in smear-negative specimens.

Table 5–23 includes the clinical and laboratory information relevant to the diagnosis of pulmonary and extrapulmonary TB.

Other nontuberculous mycobacteria, including slow-growing organisms such as *M. avium* complex and *M. kansasii*, and rapid growers, such as *M. abscessus*, can cause chronic pulmonary disease in both normal and immunocompromised hosts.

**Legionella Infections**

**Description**

*Legionella pneumophila* is a fastidious, slow-growing gram-negative rod. *Legionella* species are widespread in the environment and are a cause of community-acquired pneumonia. They are usually found in surface or potable water and are associated with moist environments. Approximately 10,000 to 15,000 cases of *Legionella* pneumonia occur each year in the United States. Most cases occur sporadically, but outbreaks have been associated with aerosolized transmission from cooling towers, evaporative condensers, potable hot water lines, showers, respiratory therapy equipment, decorative fountains, and whirlpool spas. Outbreaks in health care facilities are especially worrisome because of the large population of patients with compromised immunity or impaired pulmonary function who are at increased risk of severe *Legionella* infections.
TABLE 5–23 Evaluation for Tuberculosis (TB)

<table>
<thead>
<tr>
<th>Clinical findings</th>
<th>Pulmonary Tuberculosis</th>
<th>CNS Tuberculosis</th>
<th>Genitourinary Tuberculosis</th>
<th>Disseminated Tuberculosis</th>
</tr>
</thead>
<tbody>
<tr>
<td>Symptoms range from none to fever with productive cough and dyspnea; hemoptysis indicates presence of advanced disease</td>
<td>Fever, unremitting headache, nausea, and malaise; in the United States, elderly are frequently affected; where TB is common, it primarily affects children aged 1-5 years</td>
<td>Most common site for extrapolummary TB is the kidney; dysuria, frequency, and hematuria are common; women may present with a chronic pelvic inflammatory process, menstrual irregularities, or sterility; men may present with an enlarging scrotal mass</td>
<td>More likely to occur in HIV-positive individuals; may be present without miliary pattern in chest radiographs; patient may present with fever, weight loss, and anorexia</td>
<td></td>
</tr>
</tbody>
</table>

**Tests**

- **PPD or interferon-gamma release assay (IGRA for TB)**
  - In the presence of compatible radiologic and clinical findings, a positive PPD in an unvaccinated patient, or a positive IGRA, suggests TB; a negative result does not exclude active infection

- **Microscopy**
  - Acid-fast bacilli in sputum smears permit rapid diagnosis; sensitivity is variable, but increases with the number of specimens examined (up to 4)
  - Acid-fast bacilli in smears of CSF lead to identification of 20% or less of CNS TB cases; sputum samples also should be tested
  - Both urine and sputum samples should be examined, as a smear from a urine sample may not have detectable acid-fast bacilli
  - Urine, lymph node, liver, bone marrow, and sputum smears have low sensitivity for organism detection

- **Mycobacterial culture**
  - Culture from sputum specimen on liquid and solid media is the most sensitive method; for pediatric cases, multiple gastric lavage specimens can be used; liquid culture with DNA probe hybridization enables rapid TB confirmation
  - Culture of CSF may reveal organisms in CNS TB cases
  - Urine specimens for mycobacterial culture are positive in 60%-80% of cases, although it is more likely to be positive in men than in women
  - Culture may be performed using bone marrow, liver, urine, and sputum specimens

- **Nucleic acid amplification**
  - Very useful for rapid detection of TB but does not replace culture
  - May provide a rapid diagnosis but cannot replace culture
  - Utility not well defined
  - Sputum specimens may be used for amplification

- **Other findings**
  - Pleural fluid, if present, is an exudate (not a transudate) with mononuclear cells
  - With lumbar puncture, there may be an increased opening pressure and 100-1000 cells/μL of CSF (mostly mononuclear cells) and elevated CSF protein
  - In the appropriate clinical setting, TB may be considered if negative routine urine cultures show WBCs in acid urine
  - Impaired function of infected organs may be noted in routine laboratory tests of those organ systems

- **Radiology**
  - Chest radiograph may detect adenopathy, effusion, cavitation, or nodule; in HIV-infected patients, the chest radiograph is less likely to show typical changes
  - If TB is established in the brain, it may produce a mass, or “tuberculoma,” visible by CT scan
  - 40%-75% of cases have a positive chest radiograph; other radiologic studies are not very useful
  - Chest radiograph may be normal and repeat testing may prove useful; CT scan or MRI may be useful to detect TB in extrapulmonary sites such as the brain or vertebrae

- **Anatomic pathology**
  - Caseating granulomas may be observed in biopsies of enlarged lymph nodes
  - Biopsy may be diagnostic
  - Renal biopsy may be helpful to identify genitourinary lesions
  - If bronchial washings do not provide diagnosis, granulomas in bone marrow or liver biopsy may be diagnostic

CNS, central nervous system; CSF, cerebrospinal fluid; CT, computed tomography; MRI, magnetic resonance imaging; PPD, purified protein derivative.
Infectious Diseases

**Legionella** infections can present as subclinical infections, pneumonia, and extrapulmonary infections including endocarditis. Patients with **Legionella** pneumonia can present with a broad spectrum of symptoms, ranging from mild cough to widespread pulmonary infiltrates and multisystem failure. Patients with **Legionella** pneumonia may also experience hemoptysis, diarrhea, and a change in mental status.

**Diagnosis**

The diagnosis of legionellosis can be easily missed because the organisms are not detected on routine Gram stain (**Legionella** stains very poorly) and growth of the organism in culture requires special types of agar. A sputum Gram stain showing mostly neutrophils, without associated bacteria, should raise suspicion of Legionnaires disease or other atypical pneumonia. *L. pneumophila* serogroup 1 infections, which account for most community-acquired legionellosis, can be readily diagnosed using rapid immunoassays that detect a **Legionella** antigen that is excreted in urine. These tests detect 80% to 90% of cases and have good specificity. Another advantage is that they remain positive for several weeks, even after the patient has been started on antibiotics. Bacterial culture is the gold standard for the diagnosis of **Legionella** infection. Cultures from sputum, bronchoalveolar lavage (BAL), and/or lung tissue may require 4 to 5 days of growth for isolation of **Legionella** colonies. The sensitivity for organism detection is greater with a BAL specimen than with an expectorated sputum specimen. Isolation of **Legionella** from specimens requires the use of a charcoal-based bacteriologic medium, with the addition of antibiotics if the specimens are from nonsterile sites. The isolation and identification of **Legionella**, in association with pneumonia, is diagnostic for **Legionella** pneumonia. Direct fluorescent antibody tests of respiratory specimens are no longer recommended because they are relatively insensitive, and the specificity is greatly dependent on the experience of the individual performing the test. PCR testing and serology also may be useful in diagnosis of **Legionella** infections.

**Table 5–24** summarizes the laboratory tests relevant to diagnosis of the **Legionella** infections.

**Nocardiosis**

**Description**

**Nocardia** spp. are aerobic gram-positive actinomycetes that are found worldwide in soil and decaying organic matter. Nocardiosis is chiefly an opportunistic infection, particularly in patients with impaired cell-mediated immunity such as hematopoietic malignancies, HIV/AIDS, those receiving immunosuppressive therapy, and transplant recipients. Pulmonary nocardiosis is the most common presentation. It can exhibit the full spectrum of acute or chronic pulmonary infection, including pneumonia and abscess formation. Other clinical manifestations include anorexia, productive cough, pleurisy, dyspnea, hemoptysis, and weight loss.

PCR, polymerase chain reaction.
Primary *Nocardia* infection in the lung, skin, or soft tissue may erode into blood vessels and spread hematogenously to a variety of different organs. *Nocardia* have a well-recognized predilection for invasion into the CNS.

### Diagnosis

Detection of the organism can be accomplished by microscopic examination of specimens combined with culture. Gram staining may reveal filamentous gram-positive rods with or without branching. They are also partially acid-fast; that is, they are positive on a modified acid-fast stain (which uses a less stringent decolorizer) but are negative on a regular acid-fast stain. *Nocardia* spp. are slowly growing organisms and may be difficult to recover. Traditionally they were identified based on biochemical reactions. More recently introduced DNA-based methods reveal that many of organisms that would previously have been identified as *Nocardia asteroides* are separate species with distinct antibiotic susceptibility profiles.

The laboratory information for diagnosis of nocardiosis in different anatomic sites is provided in Table 5–25.

### Pneumocystis jirovecii Pneumonia

#### Description

*Pneumocystis* spp. are single-cell organisms that were originally described as protozoans, but phylogenetic analysis indicates that they are more appropriately classified with the fungi. These organisms are a well-recognized cause of pulmonary infection in patients with profoundly impaired cell-mediated immunity. These infections were originally attributed to *P. carinii* (which is found in rats), but it is now known that human infections are caused by the morphologically similar *P. jirovecii*. From the beginning of the HIV epidemic in the early 1980s until 1993, *P. jirovecii* was the indicator infection for more than 20,000 newly diagnosed cases of AIDS in the United States reported to the Centers for Disease Control and Prevention. It has become much less common since the introduction of highly active antiretroviral therapy. In a small number of cases, *Pneumocystis* can also cause extrapulmonary infections.

#### Diagnosis

*Pneumocystis* spp. cannot be cultured in vitro. Laboratory diagnosis depends on identification of the organism in stained preparations of clinical specimens, most often induced sputum or BAL fluid. These are concentrated onto a slide by cytocentrifugation. Other specimens include transbronchial or open lung biopsies. The *Pneumocystis* life cycle includes trophozoite and cyst stages. The most sensitive method for detecting these forms is staining the preparation with fluorescently labeled monoclonal antibodies. Other frequently used stains are GMS (stains cyst walls) and Giemsa (stains trophozoites and intracystic stages). PCR analysis of respiratory specimens may be useful in the diagnosis of *Pneumocystis*, but it is not widely available.

Table 5–26 summarizes the laboratory information that supports a diagnosis of *P. jirovecii* infection.

**Dimorphic Fungi and Other Fungal Infections**

**Description**

The dimorphic fungi grow as filamentous molds in the environment but transform into yeast (or related forms) in infected tissue. The most important members of this group are *H. capsulatum* and *Coccidioides* spp. These organisms are usually acquired by inhalation, but they can disseminate and cause life-threatening systemic infections.

*H. capsulatum* is endemic along the Mississippi and Ohio River Valleys, as well as in parts of Central America and the Caribbean region. Most infections are asymptomatic or subclinical; however, inhalation of large quantities of spores or hyphal fragments can cause symptomatic lung infection that requires antifungal therapy. As with TB, primary infection with *H. capsulatum* is contained by the cell-mediated immune response. However, the organism may not be eradicated. *H. capsulatum* infection in patients with underlying lung disease can lead to chronic progressive pulmonary histoplasmosis that must be treated to prevent further lung damage. Patients who have depressed cell-mediated immunity (due to underlying disease or immunosuppressive therapy) are at a risk of developing disseminated histoplasmosis. This form of the disease may present with nonspecific findings such as fever, weight loss, and hepatosplenomegaly, and it is fatal if untreated. Patients who harbor *H. capsulatum* and receive drugs that inhibit TNF or its receptor are also at a high risk of developing disseminated infection.

*Coccidioides* spp. are endemic in the southwestern United States (*C. immitis* in the central valley of California and *C. posadasii* in Arizona). The life cycle of *Coccidioides* is similar to *H. capsulatum* except that it forms spherules in infected tissue. Immunosuppressed patients and certain ethnic groups are at increased risk of disseminated coccidioidomycosis and CNS infections.

Immunosuppressed patients are susceptible to a variety of other fungal lung infections, including *Aspergillus* spp. and other septate molds, nonseptate molds such as *Mucor* and *Rhizopus*, and the encapsulated yeast *C. neoformans*.

**Diagnosis**

Diagnostic tests for *H. capsulatum* include fungal culture, immunoassays that detect a fungal cell wall antigen, and serology. Culture is the gold standard, but fungal growth is usually not detected for 1 to 2 weeks. Serology is useful for patients with chronic pulmonary histoplasmosis, but it is relatively insensitive for diagnosis of disseminated histoplasmosis. The antigen test performed on serum or urine is particularly useful for diagnosing disseminated disease. Coccidioidomycosis is diagnosed by serology and/or culture depending on the clinical presentation. The diagnosis of dimorphic fungal infections can also be confirmed by demonstration of characteristic structures in biopsy specimens. Currently the diagnosis of other fungal lung infections relies on culturing respiratory secretions and/or histopathologic examination of biopsy specimens. A serum assay that detects a galactomannan antigen produced by *Aspergillus* spp. is useful in the diagnosis of invasive pulmonary aspergillosis. Serum assays for circulating β-D-glucan may also be useful for detecting invasive fungal infections.

The clinical findings associated with systemic mycotic infections are shown in Table 5–27 along with the microbiologic evaluation and histopathology findings.

<sup>a</sup>The dimorphic fungi can undergo reversible transition between mold forms and yeast forms. They grow as molds in the environment but replicate as yeast (or spherules) in infected tissue.
Respiratory Virus Infections

Description
Many different viruses can cause upper and lower respiratory infections. Respiratory syncytial virus (RSV) and influenza viruses cause large numbers of infections in the winter months. RSV is the major cause of bronchiolitis in infants, and it can also cause serious infections in the elderly. Influenza is often thought of as an infection of adults (in whom it causes a syndrome characterized by rapid onset of fever, headache, and myalgias followed by upper respiratory symptoms). However, it also commonly infects children and may resemble RSV. Primary influenza pneumonia is a rare but dangerous form of the infection. More commonly, the typical influenza syndrome described above is followed several days later by a secondary bacterial pneumonia. Parainfluenza viruses classically cause croup (tracheobronchitis), the clinical manifestations of which often overlap those caused by RSV and influenza. Other important respiratory viruses include adenoviruses, metapneumovirus, and coronaviruses, including the agent of SARS. Because of the availability of antiviral agents that target influenza viruses, it has become important to establish the specific cause of virus-like respiratory particularly in severely ill patients and those with underlying cardiac and pulmonary diseases. Identification of the cause of severe respiratory infections may also be needed for infection control activities. Immunosuppressed patients are susceptible to all of the viruses described above. They are also at increased risk of developing CMV pneumonitis.

Diagnosis
The common respiratory viruses can be identified by detecting specific viral antigens in nasopharyngeal specimens (aspirates, washes, or swabs). Rapid tests for influenza can provide an answer in less than 30 minutes, but their sensitivity is only 40% to 70% (specificity is >90%). Immunofluorescent assays in which a slide preparation is stained with labeled antibodies are much more sensitive. However, they are more labor intensive and require a skilled observer. Isolation of respiratory viruses requires proper specimen collection to prevent the loss of viability of the viruses before arrival in the laboratory. Traditional viral culture methods are sensitive, but respiratory viruses typically require 3 to 10 days in culture before they can be detected. Centrifugation-enhanced culture, in which the organisms are centrifuged onto the cultured cells, can detect viruses in 1 to 2 days. Commercially available multiplexed nucleic acid amplification assays (eg, RT-PCR) can detect several respiratory viruses in 1 to 8 hours and rival or exceed the sensitivity of viral culture.

Laboratory methods for detecting respiratory viruses are summarized in Table 5–22.

INFECTIONS OF THE GASTROINTESTINAL TRACT

Overview
Although many organisms can cause infectious gastroenteritis, the clinical setting usually makes it possible to focus on a small group of likely pathogens. This is particularly important since no 1 laboratory test can detect all of the potential agents, which include viruses, bacteria, and parasites. Key factors to consider are whether the infection was acquired in the community or in a health care facility, duration of symptoms, travel history, and whether the patient is immunosuppressed.

Viruses Inducing Gastroenteritis

Description
In immunocompetent hosts, the majority of cases of community-acquired self-limited nausea, vomiting, and/or diarrhea are caused by viruses (primarily rotaviruses, noroviruses, and enteric adenoviruses [types 40 and 41]). Laboratory testing is usually not performed unless there are large outbreaks that have epidemiologic significance, for example, outbreaks on cruise ships or in health care facilities. Although enteroviruses are usually acquired by fecal–oral transmission, they generally cause systemic infections; gastroenteritis is not a prominent clinical manifestation. CMV, especially in immunocompromised patients, can produce an explosive, watery diarrhea.

Community-acquired diarrhea accompanied by abdominal pain or systemic symptoms should be evaluated for a select group of bacterial pathogens, consisting of Salmonella spp., Shigella spp., Campylobacter spp., Shiga toxin-producing E. coli, and Yersinia spp.
Table 5–28 summarizes the clinical, radiologic, histopathologic, and laboratory findings associated with the gastrointestinal illnesses produced by rotavirus, adenovirus, CMV, and noroviruses.

### Aerobic Bacterial Infections

#### Description and Diagnosis

Community-acquired diarrhea accompanied by abdominal pain or systemic symptoms should be evaluated for a select group of bacterial pathogens, consisting of *Salmonella* spp., *Shigella* spp., *Campylobacter* spp., Shiga toxin-producing *Escherichia coli*, and *Yersinia* spp. Recent travel or consumption of raw shellfish would raise the possibility of *Vibrio* spp. All of these organisms are very unlikely to be the cause of gastroenteritis in a patient who has been hospitalized for more than 3 days. Mycobacterial infections would need to be considered in profoundly immunosuppressed patients. Table 5–29 describes some of the more common bacterial infections of the gastrointestinal tract. Many of these organisms also can produce infections outside of the gastrointestinal tract.

### *Clostridium difficile* Infections

#### Description

*C. difficile* infection is frequently implicated in antibiotic-associated diarrhea. *C. difficile* elaborates toxins A and B that induce fluid secretion, mucosal damage, and intestinal inflammation and produces heat-resistant spores that persist for months in the environment. *C. difficile* infection is frequently implicated in antibiotic-associated diarrhea and is responsible for most cases of pseudomembranous colitis, a potentially life-threatening condition that requires combined medical and surgical intervention. Antibiotics frequently implicated include ampicillin, amoxicillin, cephalosporins, and clindamycin. In *C. difficile* colitis, there is a disruption of the normal bacterial flora of the colon by the antibiotic treatment, after which there is colonization by *C. difficile* organisms. Colonization of the gastrointestinal tract occurs by the oral–fecal route. *C. difficile* elaborates toxins A and B that induce fluid secretion, mucosal damage, and intestinal inflammation and produces heat-resistant spores that persist for months in the environment. The organisms can be cultured from floors, toilets, bed pans, bedding, and all sites where patients with diarrhea from *C. difficile* infection have recently been treated. *C. difficile* infection is typically acquired in the hospital by both infants and adults. Neonates have an asymptomatic colonization, and most are resistant to the toxic effects of *C. difficile* infection. Adults can also be asymptptomatically colonized. Symptomatic *C. difficile* infection usually presents with mild-to-moderate diarrhea and lower abdominal cramping. Symptoms often begin with antibiotic therapy, but may be delayed for several weeks after antibiotic therapy is initiated. Patients who go on to develop pseudomembranous colitis experience more severe diarrhea, abdominal tenderness, and systemic symptoms. Patients with advanced disease may present with a fulminant life-threatening colitis that must be treated promptly to avoid perforation of the bowel wall.

#### Diagnosis

Since patients can be asymptptomatically colonized with *C. difficile*, stool tests for toxigenic *C. difficile* should only be performed on patients with a compatible clinical presentation, such as those with 3 or more loose stools in 24 hours. Table 5–30 summarizes the evaluation of patients for *C. difficile* infection.

CT, computed tomography.
Protozoal Infections

Description

Protozoa are a very diverse group of unicellular eukaryotic organisms that can be free-living or parasitic. Many have 2 morphologic stages—trophozoites and cysts. Trophozoites, which are metabolically active feeding forms of the organism, may encyst within a protective coating to tolerate harsh environments. The cyst is a dormant form of the protozoan, and can reemerge as a trophozoite (for asexually reproducing organisms) when exposed to favorable conditions. For protozoa that multiply by sexual reproduction, a zygote is formed from the fusion of 2 gametes. Encystation of a zygote produces an oocyst that may contain 2 or more sporocysts, each with its own cyst wall. Sporocysts contain sporozoites, infective forms of the organism.

The intestinal protozoa are divided into 5 main groups that differ in terms of epidemiology and clinical presentation. Most intestinal protozoa are detected by examination of stained stool specimens.
of infection in the United States. Outbreaks have been caused by contamination of drinking water or recreational water such as pools or water parks. *Cryptosporidium* usually causes a self-limited diarrhea in immunocompetent hosts, but it can cause severe persistent diarrhea in AIDS patients. *Cyclospora* spp. have caused outbreaks linked to imported food, such as raspberries. *Isospora* infections are usually only diagnosed in immunosuppressed patients.

- **Ciliates:** *Balantidium coli* is the only pathogenic ciliate.
- **Microsporidia:** Although these organisms are included in the section on protozoans, recent phylogenetic analysis indicates that they are more closely related to the fungi. *Enterocytozoon bieneusi* causes self-limited diarrhea in normal hosts and chronic diarrhea in AIDS patients in whom it can also spread to the biliary tract. *Encephalitozoon* spp. can cause diarrhea and a variety of extraintestinal infections in immunosuppressed hosts.

**Diagnosis**

Most intestinal protozoa are detected by examination of stained stool specimens. Sensitive immunoassays are available for detecting antigens produced by *Giardia* and *Cryptosporidium*. Serology can be useful for diagnosing invasive *E. histolytica* since *E. dispar* does not trigger an antibody response. Table 5–31 describes infections produced by selected pathogenic protozoa. Protozoal infections are commonly found within the gastrointestinal tract, but, as noted in the table, many other organs and tissues can be infected.

**Intestinal Helminth Infections**

**Description**

Helminth (worm) infections in humans constitute a significant percentage of the global burden of illness caused by infectious diseases. The helminths are multicellular organisms that are divided into 3 groups: tapeworms (cestodes), roundworms (nematodes), and flukes (trematodes). Helminths are typically enclosed by a protective coat, inside of which may be differentiated organ systems for digestion, neuromuscular control, and reproduction. Many helminths have complex life cycles that involve 2 or more hosts. Helminths develop into adult worms and/or undergo sexual reproduction in the definitive host, and they do not develop past the larval stage in intermediate hosts. Infections in humans usually result from ingestion of eggs, penetration of intact skin by infective larvae, or bites by insect vectors. Many helminth life cycles involve a stage in which the larvae migrate through tissue. This migration can be relatively asymptomatic but can also have serious clinical consequences depending on the type of helminth. These principles are illustrated by the following 2 examples.

The definitive host for *Echinococcus granulosis* (a tapeworm) is the dog, which harbors the adult tapeworm in its intestinal tract and excretes eggs in the feces. When an intermediate host, such as sheep or humans, ingests these eggs, the eggs hatch in the intestinal tract and larvae penetrate the intestinal wall and eventually form slowly expanding cysts in visceral organs such as the liver or lungs.

*Strongyloides stercoralis* is 1 of the several nematodes that are acquired when infective larvae present in warm moist soil penetrate human skin. The larvae migrate through tissue into the venous circulation and are transported to the lungs where they invade the alveoli, are coughed up and swallowed, and then develop into mature worms in the intestinal tract. The adult worms produce larva that are shed in feces into the environment where they can complete their life cycle. Unlike other nematodes, however, *S. stercoralis* larvae can also penetrate the gut wall or perianal skin and initiate an autoinfective cycle that results in persistent low-level infection even after the host has left an endemic area. If an infected patient subsequently receives immunosuppressive therapy, particularly with corticosteroids, the patient can develop life-threatening *Strongyloides* hyperinfection syndrome in which large numbers of nematode larvae migrate into the lungs and extraintestinal tissues.

**Diagnosis**

Infections with intestinal helminths are usually diagnosed by detection of eggs or larvae in feces. For many of the helminths, the identification of the organism is based on the morphologic characteristics of the organism and/or the eggs. These characteristics include size, shape, and thickness of the egg wall, special structures such as knobs and spines, and the developmental stage of the egg contents (eg, undeveloped, developing, or embryonated).

CNS, central nervous system; CT, computed tomography; MRI, magnetic resonance imaging.

### Food Poisoning

Nausea and vomiting that occurs 1 to 8 hours after eating can be caused by ingestion of bacterial toxins that are already present in the food rather than by infection of the intestinal tract. The most common causes are enterotoxins produced by *S. aureus* (found in dairy and bakery products) and *Bacillus cereus* (found in reheated fried rice). The condition is self-limited. *C. perfringens* food poisoning results from the ingestion of food containing at least $10^8$ enterotoxin-producing organisms. Often these are foods that have become grossly contaminated from storage over long periods at ambient temperature. This is particularly true of animal protein foods, such as cooked meats and gravies. Most individuals experience watery diarrhea with abdominal cramps (*B. cereus* can cause a similar syndrome). Fatalities are rare, with spontaneous resolution of symptoms within 6 to 24 hours.

### Botulism

#### Description

Botulism is a neuroparalytic disease produced by potent toxins derived from *Clostridium botulinum*. The toxins block the release of the neurotransmitter acetylcholine at peripheral cholinergic synapses. The most common cause of botulism in humans is ingestion of preformed toxins in food contaminated with *C. botulinum*. Food products identified as sources of outbreaks include home-canned vegetable products, fish products preserved by a variety of methods, and sausage and ham preserved by salting rather than heating and then consumed without cooking. Infant botulism, which affects children up to 35 weeks of age only, is a result of colonization of
the intestinal tract by *C. botulinum* after the ingestion of viable spores. Wound botulism can occur when *C. botulinum* contaminates deep wounds and secretes the toxin.

Patients suffering from botulism typically present with muscle weakness, difficulty in speaking and swallowing, and blurred vision. Such patients can progress to symmetric descending weakness and paralysis that can affect the diaphragm. Constipation, nausea and vomiting, and abdominal cramping are also common presentations. Botulism toxin can be neutralized by antiserum raised against it, but the use of antitoxin may not reverse existing neuroparalysis. Recently there has been concern about the potential use of botulinum toxin as a bioweapon.

**Diagnosis**

The laboratory confirmation of human botulism is established by detection of the toxin in the serum or stool of an affected patient or in a sample of food consumed prior to onset of the illness. These assays are only available in public health laboratories. Animal assays are still used because they can detect very low levels of toxin. Isolation of *C. botulinum* from stools, gastric samples, or wound specimens, in combination with the appropriate clinical signs and symptoms for botulism, also establishes the diagnosis. For wound botulism, both serum and wound specimens should be tested for the presence of toxin and organisms. For infant botulism, stool samples are required for analysis.

The laboratory diagnosis is described in Table 5–33.

**PYELONEPHRITIS AND URINARY TRACT INFECTIONS**

**Description**

UTIs can be divided into 3 categories:

- Uncomplicated infections of the lower urinary tract involving the bladder and/or urethra
- Uncomplicated infections of the upper urinary tract, or pyelonephritis, involving the ureters, renal pelvis, and kidney
- Complicated UTIs involving various sites within the urinary tract

Acute symptomatic uncomplicated lower UTIs are very common in women. The typical symptoms are painful urination (dysuria), urgency, and frequency. Approximately 80% of these infections are caused by *E. coli*. Uropathogenic *E. coli* are genetically distinct from other intestinal strains and possess virulence factors that facilitate colonization of the urinary tract epithelium. Other enteric gram-negative rods, such as *Proteus* spp. and *Klebsiella* spp., and gram-positive cocci including *Staphylococcus saprophyticus* and enterococci can cause uncomplicated UTIs. The high incidence of UTIs in women is probably due to the relatively short length of the urethra and its proximity to the anus and the genital tract. Risk factors for uncomplicated lower UTI in young, sexually active women include intercourse and diaphragm and spermicide use. UTIs are uncommon in men until after the age of 50 years. UTIs in children are also more common in females. They can be associated with constipation, incomplete or infrequent voiding, sexual abuse, and anatomic defects within the urinary tract.

Acute uncomplicated pyelonephritis (upper UTI) is usually due to an ascending infection that begins in the bladder. The main clinical features are fever and chills, nausea, vomiting, and
abdominal pain. Costovertebral angle tenderness is usually present. Risk factors for pyelonephritis include the presence of renal stones, obstruction of urine outflow, vesicoureteral reflux, pregnancy, anatomic abnormalities of the kidney and urinary tract, and urinary catheterization. Intrarenal infections are often the result of hematogenous dissemination of *S. aureus* or *Candida* spp.

Complicated UTI refers to infections in patients with a variety of underlying conditions such as anatomic or functional urologic abnormalities, stones, or obstruction. Imaging studies are often useful for identifying the underlying problem. Other predisposing factors are indwelling catheters or urologic instrumentation, immunosuppression, renal disease, and diabetes. These infections are typically caused by hospital-acquired bacteria including *Klebsiella* spp., *Proteus* spp., *Morganella morganii*, *P. aeruginosa*, enterococci, staphylococci, and yeast.

Asymptomatic bacteriuria occurs in 3% of women; of these, 10% will develop UTIs. A higher incidence of UTIs is found in the elderly population where 10% to 15% of women older than 60 years suffer from recurrent UTIs.

### Diagnosis

The laboratory diagnosis of a UTI involves tests to detect WBCs in the urine (pyuria) and tests to detect bacteria in the urine (bacteriuria).

Rapid detection of WBCs and bacteria in the urine can be performed using a urine dipstick. The WBCs are detected with a dipstick pad containing leukocyte esterase reagents and some bacteria can be detected by their ability to convert nitrate to nitrite (see Chapter 18 for a discussion of urinalysis). WBCs and bacteria also can be identified and counted in a microscopic analysis of the urine. A urine WBC count of >5 leukocytes per high-power field is defined by most authors as significant pyuria. The level of bacteriuria in the 3 categories of UTIs varies.

Urine culture is the gold standard for the diagnosis of UTIs, although it may not be necessary for uncomplicated outpatient UTIs. Unlike most other specimen types, urine is always cultured using a quantitative procedure because interpretation of the results depends on both the type and the number of organisms in the specimen. Because urine passes through the distal urethra, which is colonized with a variety of gram-negative rods and other organisms, isolation of bacteria from a midstream clean catch urine specimen does not automatically establish the presence of infection. Significant bacteriuria is often defined as the presence of ≥10⁵ colony-forming units (CFU)/mL; however, many patients with a urethral syndrome can have lower counts. The presence of 3 or more organisms with none predominating indicates contamination, and a new specimen should be collected. Rapid specimen transport and refrigeration of stored specimens is important because bacteria can replicate in urine that is left at room temperature, unless a preservative is used, leading to overgrowth of contaminants and inaccurate colony counts. A summary of the laboratory evaluation for UTI is presented in **Table 5–34**.

CHAPTER 5 Infectious Diseases

INFECTIONS OF THE MALE GENITAL TRACT

Description and Diagnosis

Epididymitis is most often caused by a sexually transmitted disease such as gonorrhea or Chlamydia infection (discussed in a later section). However, it can also be caused by enteric gram-negative rods or Pseudomonas in patients with underlying urinary tract disease.

Acute bacterial prostatitis presents with urinary tract symptoms, a tender prostate, and is often accompanied by systemic findings such as fever. Chronic infection of the prostate due to gram-negative rods or gram-positive cocci is often asymptomatic, but it can serve as a source of recurrent symptomatic bacteriuria. Chronic pelvic pain syndromes have also been attributed to chronic prostatitis, but often the etiology is unclear. Granulomatous prostatitis caused by extrapulmonary TB or systemic fungal infections produces nodular lesions that can mimic prostatic carcinoma. Histologic examination of a biopsy specimen would distinguish these possibilities.

Table 5–35 provides an association between site of infection in the male genital tract and common causative organisms.

The most common infection of the testicle is viral orchitis that is usually caused by mumps or coxsackieviruses.

INFECTIONS OF THE FEMALE GENITAL TRACT

Description and Diagnosis

Infections of the female genital tract include vaginitis, vaginosis, and cervicitis/pelvic inflammatory disease (infection of the uterus, fallopian tubes, and adjacent structures). As with infections of the male genital tract, many of these infections are due to sexually transmitted diseases that are discussed in a later section.

The primary symptom of vaginitis is pruritus that can be accompanied by a discharge. The most common cause is the yeast Candida albicans. Trichomonas vaginalis (a protozoan) can cause a similar syndrome. The chief complaint in bacterial vaginosis is vaginal odor. In the past this

CHAPTER 5  Infectious Diseases

Infectious Diseases

condition was ascribed to overgrowth of *Gardnerella vaginalis*, but the current view is that it results from a disruption of the normal vaginal flora in which lactobacilli (gram-positive rods) are largely replaced by a mixture of gram-negative coccobacilli.

Table 5–37 briefly describes the etiologic agents, clinical features, and laboratory diagnosis of vaginitis, vaginosis, and pelvic inflammatory disease. Genital herpes and other sexually transmitted diseases are discussed in a subsequent section.

Organisms that infect or colonize the female genital tract can also cause infections of the newborn. Beta-hemolytic streptococci belonging to Lancefield group B (GBS) are also known as *S. agalactiae*. These organisms oft en asymptomatically colonize the gastrointestinal and female genital tracts; however, they are also an important cause of neonatal sepsis and meningitis (*E. coli* capular type K1 is another common cause of this type of infection). Risk factors associated with early onset neonatal infection include maternal colonization with GBS, premature rupture of membranes, chorioamnionitis, and previous delivery of an infected infant. Pregnant women are routinely screened during the third trimester at 35 to 37 weeks for colonization with GBS. This can be done by culture of vaginal and rectal swabs or nucleic acid amplification. Women who are colonized (or have the risk factors listed above) are given antibiotics during delivery to prevent neonatal infections. *Chlamydia trachomatis*, *Neisseria gonorrhoeae*, and *Herpes simplex* can also be transmitted to the newborn during delivery and cause serious infections.

### SEXUALLY TRANSMITTED DISEASES

#### Syphilis

**Description**

Syphilis is a multisystem infectious disease that has prominent dermatologic and neurologic manifestations. It is caused by *Treponema pallidum*, a thin elongated bacterium known as a spirochete. *T. pallidum* is typically spread through contact with infectious lesions during sexual activity. Transmission occurs in about one third of patients exposed to early syphilis. Primary skin lesions, also known as chancre, usually develop within 3 weeks after initial exposure. Primary syphilis is the stage defined by the presence of lesions at the site of inoculation. Secondary syphilis is the stage of hematogenous dissemination of *T. pallidum*, with widespread physical findings and constitutional signs and symptoms. The signs and symptoms include rash, alopecia, condylomata lata, and shallow painless ulcerations of mucous membranes known as “mucous patches.” Even in the absence of treatment, the signs of primary and secondary syphilis spontaneously resolve, and The primary symptom of vaginitis is pruritus that can be accompanied by a discharge. The most common cause is the yeast *Candida albicans*. *Trichomonas vaginalis* (a protozoan) can cause a similar syndrome.

</table>
patients enter a latent stage of infection. Manifestations of tertiary syphilis develop in approximately 30% of untreated patients after a variable period of latency. The manifestations of tertiary syphilis involve cardiovascular and/or neurologic and ophthalmic abnormalities. Neurologic involvement, however, is not limited to patients in the tertiary stage of the disease. The clinical manifestations of neurosyphilis include meningitis, general paresis, and tabes dorsalis. Congenital syphilis can occur in newborns whose mothers have syphilis.

The number of cases of primary and secondary syphilis in the United States was relatively stable from the early 1960s to the mid-1980s with 20,000 to 30,000 cases per year. With the appearance of AIDS and the decline of public health programs, the number of cases of primary and secondary syphilis in the United States increased to more than 50,000 by 1990; however, by 2000 it had declined by 80%. More recently there has been a gradual increase in the number of cases.

Diagnosis

*T. pallidum* organisms are too narrow to be visualized by standard light microscopy, but they can be seen by dark-field microscopy. This technique requires considerable expertise to distinguish *T. pallidum* from nonpathogenic treponemes and other artifacts, and currently it is rarely available.

*T. pallidum* cannot be cultured on microbiologic media. As a result, serologic testing is the most widely used approach for the diagnosis of syphilis. Two types of tests are routinely used. Nontreponemal screening tests for syphilis include the Venereal Disease Research Laboratory (VDRL) and rapid plasma reagin (RPR) tests. These assays detect antibodies that react with an antigen composed of cardiolipin and other lipids. A single reactive test requires supplemental historical, clinical, or laboratory information to provide a diagnosis of syphilis, as there are many biologic causes of a false-positive VDRL or RPR.

Positive screening test results are routinely confirmed with more specific tests that detect antibodies that react with *T. pallidum* antigens (ie, treponemal tests). The fluorescent treponemal antibody absorption test (FTA-ABS) uses indirect immunofluorescence to detect the binding of the patient’s antibodies to *T. pallidum* organisms fixed onto a microscopic slide (the patient’s serum is first preabsorbed with a nonpathogenic treponeme to increase the specificity of the test). The microhemagglutination assay for *T. pallidum* test (MHA-TP) measures the ability of serum antibodies to agglutinate RBCs that are coated with formalin-fixed *T. pallidum*. Because these assays are more expensive and/or technically demanding than the screening tests, they have traditionally been used to confirm a positive nontreponemal test rather than being used for initial evaluation. The introduction of high-throughput EIAs utilizing *T. pallidum* antigens has led to a reevaluation of the standard testing algorithm.

The treponemal tests are specific and sensitive, but they do not distinguish current infection from past infection. Although the nontreponemal tests are less specific, they are still very useful because changes in the antibody titer are used to monitor the response to therapy.

Diagnosis of syphilis in newborns is complicated by the fact that they can have substantial quantities of antitreponemal IgG as a result of transfer of this IgG from the maternal circulation to the fetus. A serologic diagnosis of congenital syphilis in the neonate can be confirmed if antitreponemal IgM, made by the fetus, is found in the neonatal circulation. An infant RPR titer greater than the maternal RPR titer also supports a diagnosis of congenital syphilis.

The laboratory tests used in the diagnosis of primary, secondary, latent and tertiary, and congenital syphilis are shown in Table 5–38.

**Gonorrhea**

**Description**

Gonorrhea, an infection with the organism *N. gonorrhoeae*, is a major cause of morbidity as a sexually transmitted disease, primarily because of complications of the initial infection. These complications include ascending pelvic infections in women, epididymo-orchitis in men, and disseminated gonococcal infections in women and men. Infants born to untreated mothers can also develop ophthalmia neonatorum. The clinical symptoms of gonorrhea include dysuria, urethral and/or vaginal discharge, and pelvic pain. Gonorrhea is generally more symptomatic in men than in women. Clinical features include urethral discharge and mucopurulent cervicitis,

</tbody>
</table>

respectively. Untreated asymptomatic individuals serve as a reservoir for *N. gonorrhoeae*. Transmission from males to females is more efficient than in the reverse direction. Pharyngeal infections of *N. gonorrhoeae* are typically asymptomatic.

The incidence of gonorrhea in the United States peaked in 1978 and declined approximately 75% through the late 1990s. Since then it has leveled off. Most cases are reported in men because they are more symptomatic than women. Individuals with gonorrhea have a high rate of other sexually transmitted diseases and therefore require complete screening. Ascending pelvic infections that occur in 10% to 20% of acutely infected women can result in infertility and ectopic pregnancy.

**Diagnosis**

The gold standard for diagnosis continues to be growth of the organism in culture. *N. gonorrhoeae* requires a nutrient-rich selective agar for successful culture and an incubation period of up to 48 hours for colony formation. Due to the fastidious nature of the organism, false-negative results frequently occur as a result of poor specimen handling and delayed transport. As a result of these limitations, nucleic acid amplification is now widely used to diagnose gonorrhea. These NAAT assays are as sensitive as culture when performed on cervical or male urethral swabs and provide rapid results. Several of the assays are also approved for use on urine, although the sensitivity is less for this type of specimen. These assays have high specificity, but caution must be used when interpreting positive results in a low-prevalence population. Culture is still recommended for nongenital sites. The samples collected for analysis depend on the site most likely to be infected and the sex of the patient (Tables 5–39 and 5–40).

**Chlamydial Infections**

**Description**

Chlamydiae are gram-negative, nonmotile, obligate intracellular bacteria. *C. trachomatis* is the most common cause of sexually transmitted disease in North America. It is also the agent of trachoma, a major cause of preventable blindness worldwide. *Chlamydothila pneumoniae* causes a respiratory infection that is similar to *Mycoplasma* infection. *C. psittaci*, which is common in certain birds and can be spread to humans via aerosolized feces, causes psittacosis, a respiratory and/or systemic infection.

*C. trachomatis* produces up to 4,000,000 infections each year in the United States as a sexually transmitted disease. Groups at increased risk for *C. trachomatis* infection include men or women who have had a new sexual partner or more than 1 sexual partner in the last year and sexually active women using barrier contraceptive methods. Approximately one third of infected males and half of infected females may have asymptomatic or mild infections. Subclinical infection and scarring of the fallopian tubes with subsequent infertility is 1 of the major complications of *Chlamydia* infections. *C. trachomatis* can also infect newborns during delivery.

and cause conjunctivitis and pneumonia. Lymphogranuloma venereum (LGV), a disease characterized by tender inguinal lymphadenopathy and often proctitis, is caused by specific serovars of *C. trachomatis*.

**Diagnosis**

Direct detection of chlamydial DNA using NAAT assays is now the preferred method for diagnosing genital *C. trachomatis* infections due to the high sensitivity and specificity of these assays. These tests use PCR, strand displacement amplification (SDA), or transcription-mediated amplification (TMA) to amplify *C. trachomatis* genes. They have largely replaced other nonculture methods such as antigen detection.

Diagnosis of a chlamydial infection also can be made on the basis of a positive culture of the organism from infected sites. This requires cells in which the organism proliferates and is a labor-intensive procedure. Careful sample collection and specimen transport are important in the maintenance of viable organisms for culture. Although culture is less sensitive than NAAT assays, it is still used in medicolegal situations. Commercial NAAT assays may be positive in patients with LGV, but they do not distinguish specific LGV serovars nor are they currently FDA-approved for rectal specimens. Serologic tests for anti-*Chlamydia* antibodies involving complement fixation or immunofluorescence detect antichlamydial IgG or IgM in the serum and are sometimes used to support the diagnosis of LGV.

Table 5–41 summarizes the tests available to diagnose *Chlamydia* infections.

**Herpes Simplex Virus Infections**

**Description**

HSV is a double-stranded DNA virus surrounded by a lipid envelope and is usually transmitted by person-to-person contact. The virus initially causes a productive infection of epithelial cells and then establishes a latent infection in sensory ganglia for the lifetime of the host. It can later reactivate and produce active infections. The classic pattern of infection is a group of recurring vesicles on an erythematous base; however, HSV infection is often asymptomatic, and lesions occur in a minority of infected patients. Individuals infected with HSV are potentially contagious, whether or not lesions are visible. HSVs can be subdivided into HSV type 1 and type 2. Oral herpes infections, which are typically present as cold sores, are primarily caused by HSV-1. Genital herpes infections are primarily caused by HSV-2. It is estimated that 50,000,000 individuals in the United States have genital HSV infection. Transmission of genital herpes occurs during sexual

CHAPTER 5  Infectious Diseases

Herpes simplex viruses can be subdivided into HSV type 1 and type 2. Oral herpes infections, which are typically present as cold sores, are primarily caused by HSV-1. Genital herpes infections are primarily caused by HSV-2.

contact, which is not limited to intercourse. Genital HSV-2 infection is much more likely to recur and have asymptomatic virus shedding than HSV-1 infection. Neonatal herpes may be acquired when the infant comes into contact with HSV, typically through an infected birth canal (it can also be acquired from caregivers infected with HSV). Neonatal herpes can present as a severe disseminated infection predominantly affecting the liver and lungs, as a localized CNS infection, or as a skin and mucous membrane infection.

**Diagnosis**

The laboratory diagnosis of HSV depends on the type of infection and specimen (see Table 5–42). Viral culture of vesicle fluid is useful for patients who present with genital lesions. The presence of HSV-2 infection between recurrences can be confirmed by performing type-specific serologic tests that detect antibodies to glycoprotein G. PCR testing of CSF is superior to all other methods for the diagnosis of CNS HSV infections.

LEARNING OBJECTIVES

1. Define therapeutic drug monitoring, and learn when it is necessary and how it is performed for commonly monitored drugs.
2. Describe basic pharmacokinetic principles as they relate to therapeutic drug monitoring.
3. Identify the common drugs of abuse and how they are detected in blood, serum, urine, and other body fluids.
4. Understand the association between occupations, industries, and exposure to specific environmental toxins.

INTRODUCTION

Toxicology comprises several medical applications. The analysis of drugs in human specimens can be conducted for clinical or legal/forensic purposes. Clinical applications include the acute management of overdose and therapeutic monitoring of drug concentrations to achieve maximum efficacy while limiting the toxicity and side effects of medications. Forensic applications of toxicology include analysis of drugs to provide evidence for civil and criminal court cases, to investigate the cause of death, to deter the use of performance-enhancing drugs in athletic competitions, and to determine operator impairment related to traffic citations and vehicle accidents. Workplace drug testing assesses pre-employment drug abuse and on-the-job impairment. Given the number of therapeutic drugs, drugs of abuse, and environmental toxins, as well as the variety of diseases, signs, and symptoms associated with drug exposure and overdose, there is an array of laboratory testing strategies. For this reason, the discussion of toxicology in this chapter will be divided into 3 broad sections—therapeutic drug monitoring (TDM), drugs of abuse, and environmental toxins (Figure 6–1).
Therapeutic drug monitoring

TDM is the practice of measuring the concentration of a drug or its metabolites in order to optimize the dosing of that drug to an individual patient and/or to assess patient compliance with a dosing schedule.

TDM may be required for drugs with a narrow therapeutic index, significant side effects, or low margin of safety. Monitoring is useful when the therapeutic range for a drug significantly overlaps the toxic range, when a drug cannot be dosed based on clinical observation, or when patients have compliance problems.

Not all drugs require monitoring.

Detection of drugs of abuse

An abused drug is any compound that is consumed in greater amounts or in a manner that is neither approved nor supervised by medical staff. Drugs of abuse are agents used recreationally for euphoria, stimulant, sedative, or other effects. Analysis is intended to detect past use by the patient.

Detection of environmental toxins

Environmental toxins are potentially hazardous substances that contaminate the air, water, or soil. Exposure to environmental toxins may be monitored by specific tests for clinical diagnosis and treatment.

FIGURE 6–1 Considerations in therapeutic drug monitoring, drugs of abuse detection, and detection of environmental toxins.

THERAPEUTIC DRUG MONITORING

Overview of Therapeutic Drug Monitoring

TDM is the practice of measuring the concentration of a drug or its metabolite in order to optimize the dosing of that drug to an individual patient and/or to assess patient compliance with a dosing schedule. The goal of TDM is to improve drug efficacy—the likelihood of a therapeutic effect while avoiding or minimizing adverse effects. Table 6–1 lists some commonly monitored drugs. Patients do not require monitoring for most drugs. However, for a limited group of agents or for patients with certain conditions (for instance, limited renal function, pregnancy, newborn or geriatric age groups), TDM plays an essential role in establishing the appropriate therapeutic dosing regimen.

Prior to the 1960s, drug dosing was entirely empirical. For certain agents, this trial-and-error approach gave wide variations in patient response and a significant incidence of toxicity. Since then, physicians have learned to optimize drug dosages and delivery while avoiding many of the drug’s adverse effects. This has been achieved through the development of sensitive and rapid laboratory assays and the establishment of therapeutic ranges for common medications.

Indications for Therapeutic Drug Monitoring

TDM is performed to optimize the dose of a drug to an individual patient. Drugs with a narrow therapeutic index or margin of safety (the difference between the effective dose and the toxic dose) are potential candidates for therapeutic monitoring (Table 6–2). TDM is useful for...

TDM is performed by measuring the concentration of a drug and metabolite(s). Blood or serum/plasma is the usual sample for TDM, but in some cases, urine or oral fluid samples are used to evaluate patient compliance. The most common examples of urine and oral fluid sampling are monitoring of buprenorphine, methadone, and oxycodone for compliance. By using blood levels to guide drug therapy, a proportional relationship is assumed between the plasma/serum concentration, the concentration of drug at the organ cellular level, and pharmacologic effect. For practical reasons, only blood levels of the drug are measured, because tissue concentrations cannot be easily sampled or analyzed. This pharmacokinetic principle of homogeneity defines the timing of sampling for TDM, since the concentrations of drug in blood at the moment of sample collection must reflect a proportional and constant (steady-state) concentration at the end organ and be reflective of drug effects at the cellular level. Most TDM samples are collected as trough concentrations, the lowest level just prior to the next dose, or as peak concentrations, 30 to 60 minutes after the dose, when blood levels are most reflective of the tissue concentration and drug efficacy or toxicity.

**Pharmacokinetic Principles**

Pharmacokinetics is the study of drug interaction (absorption, metabolism, and clearance) within the body. Drug behavior in the body can be described by the LADME mnemonic. The “L” stands for liberation or release of the drug from its dosage form. The “A” is absorption that describes the movement of drug from the administration site into circulation. Distribution is the “D” and describes the reversible movement of drug through the circulatory system and body tissues. Metabolism or “M” is the chemical conversion of drug to active and inactive compounds. Finally, the “E” indicates how the body eliminates the drug.

Drugs behave in the body based on their chemical characteristics at the molecular level. Drugs can be acidic, basic, neutral, or polar (Table 6–3). The charge and dissociation constant (pK) of the drug influences its absorption, distribution, and elimination characteristics. The dissociation constant of the drug also affects how the drug can be extracted from patient samples and analyzed in the laboratory.

**Liberation and Routes of Drug Administration**

Drugs can be delivered to the body in a variety of ways. Patients may take a drug orally (PO) by pill (e.g., aspirin) or dissolve a powder in a liquid drink (e.g., laxatives). Drugs can be

The chemical groups on a drug determine the drug’s characteristics and behavior in the body.

Acidic and basic chemical groups on drugs are in equilibrium between the unionized (uncharged) and ionized (charged) forms of the molecule.

Unionized forms can passively diffuse while charged forms required active transport and bind to proteins and other counterions.

Neutral drugs carry no charge and can be hydrophobic, oil-like, or polar, hydrophilic and attract water.
delivered intravenously (IV) through a needle directly into circulation (antibiotics, like vancomycin). Some medications are delivered under the tongue, sublingual (SL), like nitroglycerin for cardiac pain or angina. Others may be injected under the skin, subcutaneous (SC), like compounds in a tuberculosis test, or intramuscularly (IM), such as vaccinations. Rectal (suppositories) and transdermal (eg, fentanyl pain patches) are other methods of delivering a drug. The route of administration will affect absorption and bioavailability of the drug to the body.

### Drug Absorption

The route of drug administration and the formulation of the drug affect the rate and extent of drug absorption. For example, oral drug absorption is affected by many factors including drug solubility in enteral fluid, the acid–base characteristics of the drug, the lipid solubility of the drug, interferences with absorption by food, destruction of the drug by gastrointestinal flora, coadministration of other drugs—especially antacids, cholestyramine, and other resin-binding agents—blood flow to the gastrointestinal tract, and gastrointestinal transit time. Some orally delivered drugs are also subject to a significant “first-pass effect,” whereby they are largely metabolized by the liver to inactive compounds before reaching the systemic circulation. IV administration delivers drug directly into circulation bypassing “first-pass metabolism,” and the amount of drug delivered IV is often compared with other delivery options for determining the extent or amount of drug that is absorbed from a specific formulation. Significant variability in drug absorption is thus a common indication for TDM.

The chemical characteristics of a drug also affect the rate and extent of drug absorption. Acidic drugs carry a carboxyl group, R−COOH ([Table 6–3](#)). This acidic group is unionized or uncharged at pH levels below the drug’s dissociation constant and is ionized or charged (R−COO−) at pH levels above the drug’s dissociation constant. Drugs that act as strong acids have dissociation constants with a pK<5, such as salicylate, penicillin, and analgesics. Strongly acidic drugs are unionized and do not carry a charge at the acidic pH of the stomach while they carry a charge at the more basic pH of the intestines. So, drugs like salicylate are passively absorbed in the stomach, but require active transport for absorption across the intestines. Weak acids (barbiturates, sulfonamides, and thiazide diuretics) have dissociation constants in the range 5 to 11, and are preferentially absorbed in the intestines compared with the stomach. Strongly acidic drugs tend to be fully dissociated or charged at blood pH of 7.4 while weak acids may have significant amounts of the unionized form present in the blood. Due to the acidic pH of urine, weak acids that are ionized at blood pH may become unionized in urine and prone to greater reabsorption. Basic drugs contain an amine group (R−NH). Basic groups are ionized (R−NH₂⁺) below and unionized (uncharged) above their dissociation constant. Basic drugs can act as weak bases (eg, anesthetics, opiates, and antidepressants) with pK<10 or strong bases (eg, amphetamines and bronchodilators). Basic drugs tend to be significantly ionized (charged) at blood pH. Drugs can also be neutral and carry no charge across the range of physiologic pH. Neutral drugs can be lipophilic and act like fats (eg, corticosteroids) or polar and hydrophilic and attract water molecules (eg, digoxin).

### Distribution

After absorption, drugs distribute throughout the body through the circulatory system, lymphatic system, and tissue fluids. The amount of free drug available to act at organ receptors is affected by both protein and tissue binding. Protein binding is another consideration in TDM. Binding to plasma proteins occurs to some extent for most drugs, with bound and free (unbound) drugs existing in equilibrium. Although it is only the free drug fraction that is biologically active, most laboratory assays measure the total drug concentration, that is, the sum of the bound and the unbound drugs. Several factors can cause changes in plasma proteins and, consequently, affect free drug levels. Acid/neutral drugs tend to bind albumin while basic/neutral drugs bind α₁-acid glycoprotein. Some drugs have specific binding proteins such as cortisol and corticosteroid-binding globulin, also known as transcortin. These proteins serve as transport proteins for drugs from the site of absorption to the tissue where drug can act, and as delivery mechanisms to the liver for metabolism or the kidney for elimination. Disease alterations in protein concentration can affect the concentration of free drug. For example, hypoalbuminemia, which occurs in the elderly and
in patients with cirrhosis, may cause an increased free drug fraction in the setting of normal total drug levels. $\alpha_1$-Acid glycoprotein is an acute-phase reactant and levels of this protein increase in acute and chronic diseases. Increases in $\alpha_1$-acid glycoprotein create more binding sites for drug, so less free drug will be available in light of the same total drug concentration in a sample. The presence of uremia in disease results in compounds binding to albumin, displacing drug from the protein and elevating the free drug fraction. TDM can determine the proportion of free and total drugs in disease and individualize the dosage to the patient's condition.

**Drug Metabolism**

Drug metabolism typically renders nonpolar, lipophilic drugs into more polar, water-soluble compounds for elimination. The liver is the primary site for drug metabolism. Genetic variants, age, cirrhosis, and other hepatic conditions may adversely affect drug metabolism, and thus predispose a patient to toxicity. Many drugs are hepatic enzyme inducers or inhibitors and thus can influence the rate of their own metabolism, as well as the metabolism of many other drugs. Pharmacogenetics is study of drug action and metabolism based on genetics. Different genes can lead to changes in drug metabolism and produce an individualized response to a drug. Fast metabolizers will change parent drug to a metabolite at a greater rate than slow metabolizers, depending on the genes expressing metabolizing enzymes in the patient. For example, patients with the slow metabolizer gene will acetylate procainamide (a cardiac drug) to $N$-acetylprocainamide metabolite at a slower rate than fast metabolizers, and may be more prone to toxicity while on the same dose of drug.

**Drug Elimination**

Elimination is the removal of drug and metabolites from the body. Drug can be eliminated through the kidneys, the liver, the lungs, the skin, the feces, and by other means. Elimination of many polar, nonlipophilic drugs is achieved primarily through renal excretion, which is dependent on adequate kidney function and renal blood flow. Other parameters relevant to elimination through the kidneys include urine pH and the properties of the drug itself, such as the dissociation constant, $pK_a$, and molecular size. Drug clearance is the theoretical volume of serum/plasma that is completely cleared of a drug per unit time. Importantly, clearance is the sum of all elimination mechanisms—hepatic, renal, lung, and any other—for a particular drug. Patients with impaired drug clearance may need more frequent monitoring.

In TDM, drug levels are most often determined only after steady state has been achieved. Steady state is the condition that occurs when the amount of drug entering the system equals the amount being eliminated. Steady-state concentration is compared in relation to a target range to determine changes in dosing. The target range is established from experimental dosing studies to determine the optimum drug concentration where a drug is most effective while causing the least undesirable side effects and toxicity. The target range is a generalized range that fits most patients, but that range may need to be adjusted or altered in certain disease states and physiologic conditions. TDM allows physicians to optimize drug dosage to a patient's individual situation.

Most but not all drugs are eliminated by first-order (or linear) kinetics. This means that a constant fraction of drug is eliminated per unit time. Other drugs are eliminated by zero-order (or nonlinear) kinetics, such that a constant amount of drug is eliminated per unit time. Assuming first-order kinetics, 5 half-lives are required after initiation of drug therapy to reach nearly complete (97%) steady state (5 half-life rule). Five half-lives are also required for nearly complete clearance of a drug after the termination of therapy, and for attaining a new steady state whenever a dosing regimen has been changed.
Drug Interactions and Dose Adjustments

Many patients may take more than 1 medication, and those drugs can interact in the patient’s body. Drug interactions may cause displacement of bound drug from proteins. The clinical significance of the interaction is likely to be increased when both drugs are highly protein bound (80% or more), when 1 of the drugs has a higher binding affinity, or when 1 of the drugs is present in higher concentration than the other. Dosing adjustments may be required in these instances. Displacement of bound drug does not inevitably lead to an increased free drug level, because free drug is subject to increased metabolism and elimination. Increases in plasma proteins and drug binding may also occur as an acute-phase response or during pregnancy, and, consequently, higher dosing may be necessary. Caution must be used when interpreting total drug levels in patients with possible protein disturbances or drug interactions, and free drug levels may be more useful in these situations.

Laboratory Methods

Currently, most clinical laboratories utilize immunoassays for the rapid and quantitative measurement of therapeutic drugs. In an immunoassay, drug in the patient’s sample competes with a drug conjugate (drug attached to an enzyme or fluorescein molecule) for the binding of specific antibodies. Antibody binding results in blocking enzyme activity or in enhancing fluorescence polarization. By measuring enzyme activity or fluorescence polarization, the amount of drug in the patient sample is quantitated. Chemiluminescent immunoassays offering superior sensitivity are also available for drug analysis. Other immunoassay methods such as ELISA and radioimmunoassay are less commonly used. More complex laboratory techniques, such as chromatography with ultraviolet or mass spectral detection, are also commonly utilized for drug measurements. (See Chapter 2.) Immunoassays offer advantages over chromatographic methods, because immunoassays can be automated and analyze a greater number of samples more rapidly with less labor and cost. Only the total drug concentrations are routinely measured. Free drug levels require a more time-consuming and expensive ultracentrifugation or dialysis equilibrium steps to separate the protein-bound drug from the free drug. Free drug concentrations are typically lower than total drug concentrations by a factor of 2- to 20-fold, so more sensitive assays are required.

Specimen Collection

The appropriate specimen for therapeutic drug measurements is usually serum or plasma. Most laboratories do not accept gel separator tubes as the gel can bind drugs and interfere with drug recovery. Immunosuppressant levels are measured using whole blood due to the distribution and concentration of drug in RBCs, which are removed in the preparation of serum/plasma. EDTA-anticoagulated whole blood is the appropriate sample for these immunosuppressant drug measurements. Urine samples are frequently used to evaluate patient compliance in cases of therapeutic administration of buprenorphine, methadone, and several opiates (including oxycodone). Saliva or oral fluid may be appropriate for monitoring some medications, such as theophylline, in pediatric patients or in those for whom phlebotomy is difficult. Oral fluid is also not subject to adulteration or substitution, which can be an issue with monitoring for pain management compliance in patients prone to abuse. In general, trough levels are drawn just prior to the next dose and are used to evaluate the likelihood of a therapeutic effect. Peak levels are drawn at varying times, depending on the particular drug, and are used typically to assess toxicity risk.

Selected Commonly Monitored Drugs

Selected individual drugs and considerations for TDM are presented in Table 6–4. The required specimen volume and preservative will vary by analytical methodology, so the described collection instructions are only a guide. The reader should refer to specific instructions from the laboratory. The general monitoring recommendations will depend on the motivation for monitoring the drug, possible drug interactions, and whether the patient is stable or showing signs of toxicity. Therapeutic ranges are only suggestions and will vary by patient, condition, and the presence of other medications.

</tbody>
</table>

IM, intramuscular; IV, intravenous; PO, oral; MHD, monohydroxy carbazepine.

*Measure the sum of parent and active metabolite, that is, (amitriptyline + nortriptyline), (imipramine + desipramine), and (doxepin + desmethyldoxepin).
**Methotrexate**

Methotrexate is a folate antagonist used in the treatment of a wide variety of neoplasms. Dose-related toxicity is common with high-dose methotrexate therapy (defined as >1 g/m² or 20 mg/kg). Adverse effects include immunosuppression, and diverse organ damage including renal failure, myelosuppression, hepatic toxicity, neurotoxicity, gastrointestinal toxicity, and death. Toxicity correlates with serum methotrexate concentration and duration of exposure. Patients with poor hydration, renal insufficiency, pleural effusion, ascites, or gastrointestinal obstruction are at increased risk for toxicity. Adverse effects of methotrexate are ameliorated by administration of leucovorin, a reduced folate. Serial methotrexate levels are used to guide the appropriate dosing and duration of leucovorin rescue following high-dose methotrexate administration.

**Immunosuppressants**

The immunosuppressant drugs, tacrolimus (FK-506), cyclosporin, and sirolimus (rapamycin), are drugs used to prevent rejection in organ transplantation. Cyclosporin is also utilized to treat psoriasis, chronic autoimmune urticaria, and rheumatoid arthritis. These drugs were originally discovered in bacteria (tacrolimus and sirolimus) and fungus (cyclosporin) from soil samples. Monitoring is indicated because these drugs have a narrow therapeutic index and highly variable pharmacokinetics. Adverse effects include nephrotoxicity, hepatotoxicity, pulmonary toxicity, neurotoxicity (light sensitivity, tingling in the palms, and tinnitus), tremor, and hypertension.

Whole blood is the preferred specimen for TDM, as the immunosuppressant drugs concentrate into erythrocytes more than the plasma/serum portion of blood. Low trough concentrations may indicate subtherapeutic immunosuppression and can be associated with increased risk of rejection. High trough concentrations cause increased toxicity including nephrotoxicity that can be particularly challenging to diagnose in renal transplant patients. Drug levels must be interpreted in conjunction with other laboratory test results and clinical findings to discriminate between toxicity and rejection. For renal transplant patients on cyclosporin therapy, the only definitive method for differentiating graft rejection from drug-induced nephrotoxicity is renal biopsy. These drugs are sometimes used in combination, and with mycophenolic acid, to enhance the immunosuppressant effects and decrease the dose and side effects.

The immunosuppressants are extensively metabolized by the liver to a number of metabolites, some of which have immunosuppressant activity. Some metabolites can cross-react in laboratory immunoassays, thus overestimating parent drug concentrations in situations where elimination is impaired and when metabolites accumulate, as in cholestasis. Patients who have received mouse monoclonal antibody therapies may also have inaccurate immunoassay results. HPLC with tandem mass spectrometry is increasingly being used for laboratory analysis to circumvent cross-reactivity with the immunoassays.

**Antibiotics**

**Aminoglycosides**

Gentamicin, tobramycin, and amikacin are aminoglycoside antibiotics. Ototoxicity and nephrotoxicity from aminoglycosides are related to dose and duration of exposure. Numerous factors, such as renal and cardiac function, age, liver disease, and obesity, affect the pharmacokinetic properties of aminoglycosides. Because of the many patient factors, as well as the low margin of safety and high incidence of dose-related toxicity, aminoglycoside levels are usually indicated in conjunction with renal function monitoring to minimize toxicity. In patients with normal renal function and without underlying disease, the indication for drug monitoring is less well defined.

**Vancomycin**

Vancomycin is a tricyclic glycopeptide antibiotic with significant dose-related nephrotoxicity and ototoxicity. The practice of measuring vancomycin levels emerged from the guidelines for aminoglycoside monitoring. However, the necessity for vancomycin monitoring is controversial, because a good correlation between serum vancomycin levels and efficacy or toxicity has yet to be definitively demonstrated. Adult patients with normal renal function may not require routine monitoring. Indications for monitoring include impaired or changing renal function,
concomitant use of nephrotoxic drugs, altered volume of distribution (as in a burn injury vic-
tim), prolonged vancomycin use, higher than usual doses, and use in neonates, children, pregnant
women, and patients with malignancy.

**Antiepileptics**

Antiepileptics are frequently monitored to establish the dose necessary to reduce the frequency
and magnitude of seizures. Trough levels are used to establish minimum effective dose. When
toxicity is suspected, peak or random levels may be obtained. Too low a level will lead to break-
through seizures, while too high a dose can induce seizures. A therapeutic level maintains seizure
control and avoids side effects. The concentration of drug in the blood also may be used to evalu-
ate patient compliance, and explain seizures that are refractory to drug treatment.

**Phenytoin (Dilantin®)**

Phenytoin (or its prodrug phosphenytoin) is a widely used anticonvulsant with nonlinear kinet-
ics and wide interindividual variability in dose requirement. Phenytoin toxicity includes ataxia,
tremor, lethargy, seizure exacerbation, and neuropsychiatric changes. Phenytoin use in certain
populations requires special consideration. Neonates and the elderly have decreased clearance.
On the other hand, children metabolize phenytoin more rapidly than adults, and, therefore, dose
adjustment is necessary at various ages. Careful monitoring in pregnancy is required due to meta-
bolic and volume changes that occur during pregnancy. Phenytoin is highly protein bound, and
conditions such as renal failure, liver disease, burn injury, and age will affect the amount of free
drug by altering the amount of plasma protein.

Extensive protein binding also predisposes phenytoin to significant interactions with other
protein-bound drugs, such as valproic acid. Coadministration of valproic acid and phenytoin is
common and may cause a decrease in total phenytoin. Valproic acid displaces phenytoin from
albumin, which causes a transient increase in free phenytoin, but this free phenytoin is read-
ily metabolized and cleared. The overall effect is usually a decrease in total phenytoin with an
unchanged level of free phenytoin. Monitoring of total phenytoin levels is sufficient for patient
management, and free phenytoin levels are not usually necessary except in renal or hepatic dis-
ease, conditions that would affect total protein or body clearance.

**Phenobarbital and Primidone (Mysoline®)**

Phenobarbital and primidone are used to treat all types of seizures except absence (petit mal)
seizures. The major active metabolite of primidone is phenobarbital. Clearance of both primi-
done and phenobarbital is prolonged in neonates, the elderly, and patients with hepatic and renal
dysfunction. Phenobarbital is a potent hepatic enzyme inducer, and may affect the metabolism
and levels of many other drugs metabolized by the same enzymes. Concurrent valproic acid use
significantly decreases phenobarbital clearance.

**Carbamazepine (Tegretol®)**

The anticonvulsant carbamazepine is used not only for seizures but also for treatment of trigemi-
nal neuralgia and bipolar disorder. Monitoring of carbamazepine levels is useful due to its slow
and unpredictable absorption. Age and hepatic function affect drug clearance. Dose-related toxic
effects include blurred vision, paresthesias, ataxia, nystagmus, and drowsiness. Carbamazepine is
metabolized to the active metabolite, carbamazepine 10,11-epoxide. Children are known to accu-
mulate the epoxide metabolite and, as a result, may present with toxicity in the setting of nonel-
evated carbamazepine levels. With chronic therapy, carbamazepine induces its own metabolism,
and dosing adjustment becomes necessary.

**Valproic Acid (Depakane®, Depakote®)**

Valproic acid is used to treat all types of seizures. It is also used in the treatment of migraines and
bipolar disorder. Valproic acid has a narrow therapeutic index. Dose-related adverse effects involve
primarily central nervous system (CNS) depression. The average half-life of valproic acid is about
12 to 16 hours, but there is significant interindividual variability, and use of a sustained-release
formulation is popular. The half-life of valproic acid is prolonged in neonates and in patients with liver dysfunction. Extensive protein binding accounts for the increased valproic acid toxicity observed in patients with uremia and cirrhosis.

**Second-generation Antiepileptics**

The second-generation antiepileptics encompass a range of drugs with different chemical structures and pharmacokinetics. Some are protein bound (lamotrigine is 55% bound to albumin) while others are not (levetiracetam is <10% protein bound). Common adverse effects include dizziness, ataxia, nausea, and vomiting. Decreased hematocrit and neutropenia can also be seen with lamotrigine. In general, the second-generation antiepileptics have a wider therapeutic index and fewer side effects than the first-generation drugs. HPLC and immunoassays are available. However, therapeutic and toxic ranges have not been established for all of these drugs. So, monitoring is generally conducted to define the individual level at which a patient is achieving therapeutic action with fewest side effects for future reference, for compliance, and for documentation of the level at which side effects are evident for that patient.

**Antidepressants**

**Tricyclic Antidepressants**

Tricyclic antidepressants are monitored for multiple reasons. There is significant interindividual variation in metabolism and elimination, such that standard dosing results in therapeutic levels in less than half of patients. Genetic variation accounts for some of this variability. The fraction of “poor metabolizers” is about 17% of Caucasians and 5% of other ethnic groups. Other indications for monitoring include a narrow therapeutic index, multiple drug interactions, and patient compliance.

Tricyclic antidepressants have a low margin of safety and cause anticholinergic toxicity, seizures, and arrhythmias in overdose. Although the correlation between toxicity and blood level is poor, there are general guidelines. Levels in excess of 500 μg/L may be associated with anticholinergic toxicity (flushing, tachycardia, fever, dilated pupils, dry mucous membranes, urinary retention, and absent bowel sounds). Cardiotoxicity is more likely to occur at levels greater than 1000 μg/L in acute overdose.

**Lithium**

Lithium is a univalent cation most commonly used to treat bipolar disorder. Lithium monitoring is useful due to its narrow therapeutic index and the wide interindividual variation in dose requirement.

Excretion of lithium is primarily renal. Children have increased clearance, while the elderly have decreased clearance. Lithium excretion parallels sodium excretion. Therefore, patients on stable doses of lithium may become toxic in states of sodium conservation such as fever, excessive sweating, lack of fluid intake, and diarrhea.

Toxicity is usually associated with levels in excess of 1.5 mmol/L. However, toxicity may occur at lower levels, especially in cases of chronic toxicity. Lithium overdose is characterized by lethargy, weakness, slurred speech, ataxia, tremor, and myoclonic jerks. Severe toxicity may result in seizure, hyperthermia, and coma. Management of patients who have ingested sustained-release lithium preparations is difficult, and serum measurements play a crucial role in the decision to instigate hemodialysis or whole bowel irrigation. Analytical methods involve the use of ion-specific electrodes, and spectrophotometry or colorimetric tests.

**Later-generation Antidepressants**

Fluoxetine was the first selective serotonin-reuptake inhibitor used to treat depression. Fluoxetine monitoring is useful when patient compliance is in question. Further monitoring is not likely to be beneficial since fluoxetine has a wide therapeutic index, and there is a poor correlation between blood levels and clinical response. Fluoxetine is metabolized by the liver to the active metabolite norfluoxetine.

Other serotonin-reuptake inhibitors/later-generation antidepressants—such as sertraline (Zoloft®), paroxetine (Paxil®), fluvoxamine (Luvox®), citalopram (Celexa®), quetiapine (Seroquel®),
trazodone (Deseryl®), and venlafaxine (Effexor®)—do not require routine monitoring due to their wide therapeutic indices.

**Cardiac Drugs**

**Digoxin**

Digoxin is a commonly used drug in the treatment of heart failure and arrhythmias, and it has a low therapeutic index. There is significant interindividual variation in digoxin absorption and distribution along with prolonged clearance in patients with impaired renal function. Digoxin overdose is characterized by gastrointestinal distress, confusion, visual changes, hyperkalemia, and life-threatening cardiac toxicity. Overdoses may be treated with an antidigoxin antibody antidote. Such treatment typically renders subsequent blood digoxin concentrations unreliable. Blood digoxin immunoassays are generally less reliable than immunoassays for other therapeutic agents. Interferences with digoxin immunoassays are frequently reported. These interferences are referred to as digoxin-like immunoreactive substances ("DLIS").

**Pain Management**

**Acetaminophen**

Acetaminophen is a therapeutic drug used as an analgesic and an antipyretic. When it is used in the recommended doses, it is not necessary to measure acetaminophen levels. However, excess intake of acetaminophen can be associated with severe liver injury. Thus, acetaminophen is a representative of many compounds with a wide therapeutic window that does not require therapeutic monitoring when used in recommended doses. However, because toxicity can occur if the upper limit of the window is exceeded, monitoring acetaminophen levels in patients with excess intake is critical, particularly since an antidote to the major toxic effect can be administered. Table 6–5 presents an overview of the laboratory evaluation for acetaminophen toxicity. Immunoassays are available for the rapid determination of serum/plasma levels.

Acetaminophen is rapidly absorbed from the gastrointestinal tract. The plasma concentration reaches its highest level 30 to 60 minutes after a dose. One of the compounds resulting from acetaminophen metabolism is an oxidation product that is hepatotoxic. Normally this metabolite is detoxified by binding to glutathione in the liver. With excess intake of acetaminophen, the production of the toxic metabolite exceeds the amount of hepatic glutathione, and this permits the toxic metabolite to produce liver injury. Renal damage also may occur as a result of injury by the same compound.

<tr>
<td>Laboratory monitoring of acetaminophen concentration</td>
<td>The importance of laboratory monitoring is related to the use of <em>N</em>-acetylcysteine as a treatment for the acetaminophen overdose; it is important that the neutralizing effect of <em>N</em>-acetylcysteine be provided before acetaminophen metabolites produce liver injury. To determine whether the acetaminophen ingestion is likely to cause liver toxicity, a 4-h post-ingestion serum concentration should be obtained; the serum concentration of the drug will be used to determine if the patient is likely to experience liver injury and, if so, treated with <em>N</em>-acetylcysteine. If the first acetaminophen level is obtained more than 4 h post ingestion, a nomogram can be used (available in many textbooks) to determine if the acetaminophen level at that time post ingestion is likely or not likely to be associated with liver injury.</td>
</tr>
<tr>
<td>Liver function tests</td>
<td>Hepatic necrosis becomes evident 24-48 h after the ingestion of the excess amount of acetaminophen if the patient is not treated; at that time, standard liver function tests such as AST (SGOT), ALT (SGPT), bilirubin, as well as the prothrombin time, can be used to assess the extent of liver injury.</td>
</tr>
</tbody>
</table>

ALT, alanine aminotransferase; AST, aspartate aminotransferase. The prothrombin time is a good prognostic tool when used as an indicator of hepatic recovery.
The recommended daily dose of acetaminophen is no more than 4 g per day. A single dose of 10 to 15 g may produce liver injury. Fatal disease is usually associated with ingestion of ≥25 g of acetaminophen. Acetaminophen at slightly more than the recommended 4 g per day can produce hepatotoxicity when the patient has also ingested ethanol, and this response can be exacerbated if the patient had been fasting prior to ingestion of acetaminophen and ethanol, or takes another enzyme-inducing drug such as phenytoin. The ingestion of acetaminophen at greater than recommended doses produces corresponding elevations of acetaminophen in the blood, and the level of the drug in the blood correlates with the severity of hepatic injury.

Acute manifestation of excess acetaminophen intake typically occurs 2 to 3 hours after ingestion. Most often this includes nausea, vomiting, and abdominal pain. Cyanosis of the skin and fingernails may be observed as a result of methemoglobin generation from the overdose. The full extent of liver damage usually becomes apparent 2 to 4 days after drug ingestion. At that time, liver function test results, including the prothrombin time, become abnormal. A variety of associated abnormalities, including electrolyte disturbances, can occur if there is significant liver damage. Acute renal failure also may occur, even if liver failure is not observed.

Aspirin

Aspirin (acetylsalicylic acid) is a therapeutic drug in use for more than a century as an analgesic, antipyretic, anti-inflammatory, and antithrombotic agent. It is readily absorbed and rapidly metabolized by hydrolysis to salicylic acid. Peak concentrations occur within 1 to 2 hours with a therapeutic dose. Between 50% and 90% is bound to albumin in a dose-dependent manner. Further metabolism produces salicyluric and gentisic acids and glucuronide conjugates that are renally excreted. Aspirin is contained in many preparations, including those with other analgesics. When used in therapeutic doses, it is not necessary to measure levels. However, chronic salicylate poisoning (salicylism) carries a high morbidity (30%) and mortality (25%), and is difficult to diagnose without monitoring levels since the patient may be too confused to give a reliable history. Table 6–6 presents an overview of the laboratory evaluation for salicylate toxicity. Immunoassays are available for the rapid determination of serum/plasma levels. About 500 mg/kg as an acute dose is potentially lethal in comparison to a normal dose of 15 mg/kg. When taken in therapeutic doses, the half-life

| Detection of aspirin metabolites in urine by color test (Trinder reagent); monitoring of serum salicylate concentration by enzymatic assay or immunoassay | The importance of these tests is to establish the diagnosis of poisoning. Since a number of preparations are available containing sustained-release aspirin, it is recommended that serial blood samples be drawn at 3-h intervals to determine whether the drug concentration is still rising. The Done nomogram interprets the serum salicylate concentrations taken at 6 h after acute ingestion as follows:  
- <50 mg/dL: asymptomatic  
- 51-110 mg/dL: mild-to-moderate toxicity  
- >110 mg/dL: serious toxicity  
The use of the Done nomogram is unreliable when:  
- There has been a previous ingestion within 24 h  
- Poisoning is chronic (concentrations >30 mg/dL indicate serious toxicity)  
- Enteric-coated or sustained-release preparations have been ingested  
- Renal failure is present  
Treatment for aspirin overdose is symptomatic and supportive—administration of repeat doses of oral activated charcoal may be given in an attempt to prevent further absorption and increase fecal elimination. Bicarbonate is used to counteract the metabolic acidosis, and calcium and electrolytes are administered to prevent seizures and cardiac failure. Hemodialysis may be indicated at concentrations above 100 mg/dL. (>40 mg/dL in chronic salicylism), and to support renal function and electrolyte balance.  
Regular monitoring of renal function, blood gas and lactate, and coagulation assessment are important for patient care. |
Toxicology

is 2 to 5 hours, but metabolism becomes saturated once the dose exceeds about 30 mg/kg, causing a
delay in drug elimination. An early feature of toxicity is respiratory alkalosis through direct stimu-
lation of the respiratory drive center, followed by vomiting. The latter mechanism of toxicity results
from uncoupling of oxidative phosphorylation, leading to ketosis, metabolic acidosis, and pyrexia,
with further dehydration and electrolyte imbalance. Hematologic consequences arise that manifest
as an increased prothrombin time, GI bleeding, and occasionally DIC.

Other Pain Management Drugs

Buprenorphine and methadone are analgesics that are commonly utilized for opiate withdrawal,
but have found recent medical application in the management of chronic pain. Fentanyl and oxy-
codone are other drugs utilized in pain management that may be monitored. Serum/plasma levels
of these drugs correlate poorly with clinical effect because of tolerance. The safety of these drugs
in doses utilized for pain management does not typically require monitoring and dosing can be
adjusted based on pain relief. However, these drugs have high abuse potential, so urine tests are
sometimes used to monitor for compliance and ensure that the patient is not diverting the drug
for sale or other purposes. Immunoassays are available for analysis of these drugs in urine samples.

DRUGS OF ABUSE

Overview

Drug of abuse testing (DAT) includes testing for the use of illicit drugs, and potentially addictive
or harmful therapeutic agents.

The goal of drug of abuse testing is to detect past exposure or use of a drug. Quantitative levels of a
drug or its metabolite in fluids are not required. Laboratory analysis determines if a drug is above (ie, “present”) or below (absent) a defined cutoff concentration in the sample.

Table 6–7 lists the typical detection window for analysis of common drugs of abuse.

Drugs and their metabolites are much more concentrated in urine than in serum. Urine is the
specimen of choice for DAT testing because of its ready availability. Other specimens have also
been utilized for DAT. Meconium (an infant’s first bowel movement after birth) has been utilized
to detect in utero exposure of a fetus to drugs. Since meconium is made during the last trimester
of fetal development, drug exposure can be detected from as early as the sixth month of gestation.
Hair and nails have also been analyzed in attempts to detect drug use over a longer time frame
than urine, but the clinical utility of specimens other than urine remains controversial.

Analysis for multiple drugs in a patient’s sample can be labor intensive and expensive. Laboratory analysis for drugs of abuse thus takes a 2-tier approach for efficiency. A simple, rapid assay that can be readily automated is used to first screen a sample for the presence of a class of drugs. These screening tests are sensitive and designed to detect a broad range of similar drugs that share a common chemical structure. Unfortunately, screening tests are generally not very specific and subject to a variety of cross-reactivities that can lead to false-positive test results. Thus, a second tier of more specific testing is conducted to “confirm” the presence of a particular drug in samples that screen positive. Common screening tests are immunoassays that can be readily performed on chemistry instrumentation in a clinical laboratory or on point-of-care devices for testing in a variety of settings outside of a formal laboratory. Table 6–8 lists the cutoffs and other characteristics of immunoassay tests. Most immunoassays detect a number of drugs within a class of agents, but some immunoassays are specific to a given compound, like the metabolite of cocaine, PCP, oxycodone, and 6-monoacetylmorphine.

</table>
The second-tier or “confirmatory” testing employs a chromatographic separation prior to mass-spectrometric detection to exactly identify the drug or metabolite in samples that generated a positive immunoassay screen. (See Chapter 2.) Confirmatory testing is expensive and time-consuming, but is absolutely required for forensic, legal, pre-employment, and other applications of the test result that mandate definitive analysis. Confirmatory testing can take several days and will not assist in the immediate care and management of a trauma or acute overdose patient.

The lack of confirmatory testing on clinical samples can lead to misinterpretation of test results unless the clinician maintains an active dialogue with the laboratory regarding the likely causes of false-positive screening tests. Many laboratories append a comment to warn that positive urine immunoassay results have not been confirmed. Common causes of false-positive test results may also be listed with the result.

Common drugs that cause cross-reactivity and false-positive DAT results are listed in Table 6–8. Cross-reactivity and the causes of false-positives are dependent on the antibody specificity employed in the immunoassay, so cross-reactivities will vary from 1 manufacturer to another and between laboratories based on the method utilized for analysis. Clinicians should be familiar with the characteristics and limitations of the drug tests employed to analyze patient specimens.

Drugs of abuse have no reference or therapeutic range, because the drug should not be detected in the patient’s sample. However, sometimes a positive drug test is desired by the ordering physician. Urine oxycodone, for example, is utilized for pain management, but can also be sold by a patient for monetary profit. A positive urine oxycodone test is targeted to assure that patients are compliant with their drug regimen and not diverting the drug for other purposes.

Screening for drugs of abuse does not detect every possible drug that the patient may have ingested. Laboratory analysis is limited to the specificity of the tests at hand. Patients may have access to a wide variety of plants that contain toxins or medications for which the laboratory does not test. In general, drug analysis is designed for rapid identification that may permit effective treatment (eg, acetaminophen and its antidote) to reduce the toxic effects of the compound. Concomitant ingestion of different drugs is very common and may play a role in laboratory analysis for drugs of abuse. For example, alcohol and cocaine are often ingested together, and patients ingesting these drugs together can form a toxic metabolite called cocaethylene.

**Specimen Collection and Laboratory Analysis**

The potential for sample adulteration is a concern for any DAT. False-negative results can be caused by purposely “adulterating” a urine sample to prevent the immunologic or indicator reaction from working, leading to a false-negative result despite drug in the sample. Common household chemicals such as bleach, vinegar, sodium bicarbonate, Drano, soft drinks, or hydrogen peroxide may be added to a urine sample in an effort to cause false-negative results. Many of these additives work by changing the sample pH, to denature the antibody proteins used in the assay or to shift the pH away from optimum assay conditions. Such adulteration can be detected by checking the pH of urine samples submitted for drug testing. Other adulterants include glutaraldehyde or nitrites, and can be analyzed using specific tests for adulteration in the laboratory.

Patients can take diuretics to temporarily enhance elimination. Diuretics cause an increase in urine output, so drugs that may be present will be diluted below the assay cutoff concentration in the urine sample. Alternatively, patients may submit water as their urine sample, so as to avoid detection of drug use. Collection facilities can deter sample dilution by monitoring the temperature of samples just after collection. Samples outside a physiologic temperature range should be suspected of dilution. Facilities can also cap hot water faucets and add bluing agents to the toilet water as additional deterrents. Laboratories can test for urine osmolality and look for specimen dilution by analysis of urine creatinine.

Patients may also try to avoid detection by substituting specimens. Submission of someone else’s urine as a patient sample is perhaps the hardest for laboratories to detect. Sources of drug-free urine are readily available via the Internet, and these materials are used by patients trying to avoid detection of their drug use. In nearly all standard tests, these materials act like normal, unadulterated human urine. Without close monitoring of a patient during urine sample collection, sample substitution is nearly undetectable by laboratory methods.
When evaluating a patient for drug use, collecting an appropriate specimen is an important step to detecting the presence of a drug.

- Most drugs and metabolites are concentrated in urine after use. Urine is appropriate for qualitative analysis (presence/absence of drug) and for determining recent use of amphetamines, benzodiazepines, barbiturates, cannabinoids, cocaine metabolites, opiates, and their metabolites (including codeine and morphine), oxycodone, and PCP. Urine is easy to collect and noninvasive, but subject to adulteration, dilution, and sample substitution. Monitoring of urine collection is intrusive of patient privacy, so facilities collecting urine samples should take steps to deter adulteration (capping hot water faucets and using bluing agents in the toilets) and have patients remove coats and bulky clothing, and keep purses and backpacks out of the bathroom during collection.

- Serum/plasma and blood samples provide a single time point of drug in the patient’s system. Since blood is in equilibrium with tissue and organ receptors at steady state, quantitative blood levels of drug can assess for intoxication and toxicity. Serum, plasma, and blood concentration are useful for analyzing alcohol intoxication, management of analgesic overdose (including acetaminophen and salicylates), and evaluation of TDM side effects and toxicity. Collection of blood requires a needlestick and phlebotomy, but is not subject to sample adulteration like urine samples.

- Other body fluids may prove useful: meconium for evaluation of in utero exposure to drugs, vitreous humor for postmortem examination, hair and nails for past exposure to certain drugs of abuse and toxins, and sweat or oral fluid that can be collected without invasion of privacy and are less prone to adulteration.

It is essential that specimens are collected at an appropriate time following ingestion and that the sample is properly preserved. Serial measurements over time may be necessary because of delayed gastric emptying or prolonged absorption from sustained-release preparations in overdose cases. Blood levels do not necessarily correlate with the severity of toxicity because many compounds distribute into specific body compartments or cells, and are therefore less detectable in blood. The detection of drugs in urine will depend on the patient’s renal function and urine output, the time since last dose, chronic use of the drug, the patient’s hydration state, and metabolism. Thus, urine collection within the first several hours after use has a better chance of detecting drug than urine collected several days after use. Not all drugs are equally stable in a body fluid. Alcohols should be collected anaerobically, as they are volatile compounds that will dissipate when exposed to air. Appropriate steps should be taken to preserve the drug in the specimen after collection prior to analysis.

**Selected Drugs of Abuse**

**Amphetamines**

Amphetamines are stimulants and common class of abused drugs. Methamphetamine (crank, speed), 3,4-methylenedioxyamphetamine (a derivative of methamphetamine, also known as MDMA or ecstasy), and several other amphetamine derivatives are used orally and intravenously as illicit drugs. A smokable form of methamphetamine is known as “ice.” Amphetamine-like drugs also can be used as prescription medications for treatment of a variety of conditions and disorders. These include weight loss, narcolepsy, attention deficit disorders, and sinus congestion. Amphetamine-like drugs work primarily by activating the sympathetic nervous system via the CNS. Drugs in this class can produce toxicity at levels only slightly above the usual doses, but a high degree of tolerance can develop after repeated use. Patients who are intoxicated with amphetamine-like drugs present with CNS effects that can extend from euphoria to seizure and coma. More severe signs and symptoms are usually associated with greater amounts of drug ingestion. The acute peripheral manifestations extend from sweating and tremor to myocardial infarction, even if the coronary arteries are normal. Death in amphetamine users can be caused by ventricular arrhythmia. The ingestion of amphetamines and related drugs can be conclusively established by identification of these compounds in urine or in gastric samples. Quantitative serum levels often do not correlate with the severity of the signs and symptoms.
Barbiturates
Barbiturates are used clinically as hypnotic and sedative agents, for induction of anesthesia, and for treatment of epilepsy. Ultrashort-, short-, intermediate-, and long-acting barbiturates have different pharmacokinetic properties. All barbiturates cause a generalized depression of neuronal activity in the brain. The toxic dose of barbiturates depends on the specific barbiturate used, the route and rate of administration, and individual patient tolerance. Toxicity is likely to appear when the dose administered exceeds 5 to 10 times the hypnotic dose, but chronic use may result in marked tolerance. The patient with mild-to-moderate intoxication of barbiturates often presents with lethargy, slurred speech, nystagmus, and ataxia. With greater amounts of drug ingestion in overdose, hypotension, coma, and even respiratory arrest can occur. Barbiturates can be detected in both urine and serum to document their ingestion.

Benzodiazepines
Benzodiazepines are sedatives, and antiepileptic and antianxiety medications. The different benzodiazepines vary in potency, duration of effect, and conversion to active and inactive metabolites. Benzodiazepines produce a generalized depression of spinal reflexes and may cause coma. Death from benzodiazepine overdose is rare unless the drugs are used in combination with other compounds, such as alcohol. Oral overdoses of diazepam (Valium®) have been reported in excess of 15 to 20 times the therapeutic dose without serious depression of consciousness. However, if the same drug is given at a much lower concentration with rapid intravenous injection, respiratory arrest can occur. Although there is variability among benzodiazepines, the onset of CNS depression is typically observed 30 to 120 minutes after ingestion. Drug levels can be obtained from both serum and urine specimens. However, because levels are rarely of value in emergency management, quantitative analysis is often not conducted. Of the benzodiazepines, clonazepam, used in the treatment of absence seizures, is the most often monitored, especially in children, although most patients are managed without monitoring. There is little evidence for a therapeutic window, probably because receptor effects do not mirror plasma concentrations, and tolerance can develop with continued use. HPLC is used for quantitative analysis in serum/plasma, but the presence of drug can be detected in urine by immunoassay.

Cannabinoids
Cannabis derivatives include marijuana and hashish. Marijuana consists of the leaves and flowering parts of the plant Cannabis sativa. Marijuana is usually smoked in cigarettes or pipes, and can be ingested in food. Dried resin from the plant can be compressed into blocks to make hashish. The primary psychoactive cannabinoid in marijuana is delta-9-tetrahydrocannabinol (THC). THC is also available in capsule form as a treatment for nausea in patients being treated with chemotherapeutic agents and those undergoing treatment for glaucoma. The effects of THC are related to the dose and time after consumption. THC may be a stimulant, a sedative, or a hallucinogenic compound. A typical marijuana cigarette contains 1% to 3% THC, but some may contain up to 15% THC. Hashish contains 3% to 6% THC, and an oil extract can be prepared from hashish with 30% to 50% THC. Significant variability in toxicity exists between individuals, which is influenced by prior exposure to the drug and degree of tolerance. The clinical presentation of a patient after use of THC can vary from euphoria and a heightened sensory awareness to impaired short-term memory, depersonalization, visual hallucinations, and acute paranoid psychosis. THC use can be established by detection of the drug in the urine. However, drug levels correlate poorly with the degree of intoxication. A urine test for cannabinoids may be positive for 10 to 25 days after the last exposure in moderate to heavy use. In fact, there are well-documented reports of true-positive test results in chronic use more than 80 days after last exposure to THC.

Cocaine
Cocaine is a stimulant drug. It may be sniffed into the nose, smoked, or injected intravenously. The “free base” form of cocaine is preferred for smoking because it volatilizes at a lower temperature and is not as easily destroyed by heat as the hydrochloride salt of the drug. Crack cocaine is a dried form of the drug that has been mixed in alkaline aqueous solution to generate the free base. Cocaine can also be combined with heroin and injected as a “speed ball.” The primary
CHAPTER 6  Toxicology

Effect of cocaine is generalized sympathetic stimulation, very similar to that produced by amphetamines. There is also a depression of cardiovascular function as a result of decreased cardiac contractility. The toxic dose depends significantly on the tolerance of the individual to the drug, the route of administration, and whether the cocaine is administered with other compounds. A dose that produces only euphoria when swallowed or snorted can produce convulsions and cardiac arrhythmias when rapidly injected intravenously or smoked. The initial euphoria from exposure to cocaine can be followed by anxiety, agitation, hyperactivity, and seizures. With high doses, respiratory arrest can occur. Death can result from fatal arrhythmia, status epilepticus, intracranial hemorrhage, or hyperthermia. Cocaine use can be detected through analysis of the primary metabolite, benzoylecgonine, in the urine, although parent drug and metabolites can also be analyzed in plasma/serum or in vitreous humor in death investigations.

Opiates and Opioids
Opiates are narcotic sedatives and analgesics used for pain management. They are naturally occurring compounds extracted from the poppy *Papaver somniferum*. Opioids include the naturally occurring opiates and their derivatives (morphine and codeine) and the synthetic opioids (dihydrocodeine, heroin, hydromorphone, oxycodone, and oxymorphone). Many prescription medications contain opioids. Mixtures of aspirin or acetaminophen with an opioid compound, such as codeine, are in common use. Dextromethorphan is an opioid derivative that is used to suppress cough. This compound can be obtained without a prescription as it has no analgesic or addictive properties. Morphine is an opioid that is widely used in medicine to reduce pain. The best known drug of abuse in this category is heroin. In general, all opiates and opioids cause sedation and respiratory depression. Toxicity is related to respiratory failure that can lead to death. The toxic dose varies widely with the opioid administered, its route and rate of administration, and the individual’s tolerance to the drug. Diagnosis of opiate intoxication may be established clinically when the typical signs and symptoms are present—pinpoint pupils, and respiratory and CNS depression. These symptoms are reversed by administration of the opioid antagonist naloxone. Opioid use can be determined in urine using immunoassay. Specific immunoassays can detect the presence of methadone, fentanyl, and buprenorphine while chromatographic techniques can analyze meperidine and tramadol. Levels of these compounds in serum/plasma, however, are not usually analyzed, because opiate concentration correlates poorly with clinical effects.

Oxycodone is synthesized from thebaine, a natural constituent of opium. It is available in a number of compound analgesics, with acetaminophen and aspirin. Oxycodone abuse has grown over the last decade, and specific immunoassays are available for this drug, since most broad-spectrum opiate class immunoassays fail to detect oxycodone in the clinically relevant concentration range.

Phencyclidine
PCP is an anesthetic agent that became popular as an inexpensive street drug in the late 1960s. It is most often smoked, but it can be snorted, ingested orally, or injected. It is commonly used in combination with other illicit drugs. Ingestion of PCP produces a generalized loss of pain perception and can cause hallucinations, euphoria, and disinhibition. Ingestion of large amounts can produce death, often from self-destructive behavior or from complications of hyperthermia. PCP use can be detected in the urine using immunoassays. PCP levels in the serum are not clinically valuable, because drug levels do not correlate with the degree of intoxication.

Alcohols: Ethanol, Methanol, Ethylene Glycol, and Isopropanol
Ethanol is the most common drug of abuse. Many patients presenting to hospitals with altered mental status suffer from excess ethanol ingestion. Ethanol is present not only in beverages but also in many medications. Ethanol intoxication is associated with many different types of accidental injury, particularly those involving motor vehicles. Chronic abuse of ethanol can lead to pancreatic disease and liver cirrhosis.

Ethanol is rapidly absorbed from the gastrointestinal tract. It distributes into the total body water and diffuses freely into the tissues. Peak blood ethanol levels occur 30 to 75 minutes after
ethanol ingestion. Food ingestion can delay absorption. A useful rule of thumb is that 1 oz of 80 to 100 proof spirits, 4 oz of wine, or 12 oz of beer increases the blood alcohol concentration by 25 to 30 mg/dL when ingested over a period of several minutes. The blood ethanol level in a nonchronic alcoholic decreases at a rate of 15 to 25 mg/dL/h once ethanol ingestion is discontinued. The blood ethanol levels required to induce fetal alcohol syndrome have not been determined. Pregnant women who abuse ethanol have a high risk of delivering an infant with fetal alcohol syndrome. These infants have prenatal growth retardation, dysfunction of the CNS, and characteristic craniofacial abnormalities. Because an acceptable lower limit of alcohol intake in pregnancy has not been defined, pregnant women are generally advised to abstain from ethanol.

Metabolism of ethanol occurs by an oxidative pathway to acetaldehyde and acetic acid, and, also, by a nonoxidative pathway to fatty acid ethyl esters. When the acetaldehyde is subsequently converted to acetic acid, acidosis can occur. The major metabolizing enzyme for oxidation of ethanol to acetaldehyde is alcohol dehydrogenase, and a second enzyme is the cytochrome P450 system. The cytochrome P450 enzymes are liver microsomal enzymes involved in the metabolism of several drugs. Cytochrome P450 enzymes can be induced to higher levels of activity by ethanol. Ingestion of ethanol can thus alter the metabolism of a number of drugs, which are metabolized by this same system. Induction may increase or decrease the therapeutic and/or toxic effect of drugs. Ethanol can also compete with drugs for metabolism by the cytochrome P450 enzymes.

The measurement of blood ethanol concentration can be performed by breath analysis, or more accurately, by an enzymatic assay or a gas chromatographic test that can measure ethanol, methanol, and isopropanol, individually.

### ENVIRONMENTAL TOXINS

#### Overview
Monitoring of environmental toxins is a significant challenge because so many substances that can produce illness and even death are encountered in daily life. Occupational exposure to heavy metals, gases, and caustic compounds can occur in the workplace, and leaching of toxins from an industry can contaminate soil and groundwater, leading to exposure of food sources, drinking water supplies, and livestock. Carbon monoxide, mercury, cyanide, and insecticides are some of the notable environmental toxins. Lead exposure can occur from occupational and nonoccupational sources (such as paint chips) and produce subclinical to life-threatening illness, depending on the amount ingested. Low-level exposure in children can produce serious disease and affect long-term mental development.

Laboratory analysis of an environmental toxin may not always measure the compound directly. In some cases, the toxin impairs flow through a metabolic pathway. Accumulated metabolites can be measured that reflect the toxic effects rather than a direct analysis of the toxin. Insecticide exposure, for instance, can be measured indirectly by cholinesterase enzyme activity rather than direct analysis of the insecticide levels in the body.

#### Carbon Monoxide

**Description**
Carbon monoxide poisoning is responsible for up to 4000 deaths per year in the United States and is the leading cause of accidental and deliberate poisonings. The principal pathologic consequence of carbon monoxide poisoning is the binding of carbon monoxide to oxygen-binding sites in the hemoglobin molecule.

effects of carbon monoxide. Carbon monoxide can also impair vision, hearing, and peripheral nerve conduction. The poisoning may be sublethal and cause cardiac dysrhythmias, myocardial ischemia, headache, and a variety of other signs and symptoms. Survivors can suffer permanent, severe neurologic impairment.

The principal pathologic consequence of carbon monoxide poisoning is the binding of carbon monoxide to oxygen-binding sites in the hemoglobin molecule. The binding of carbon monoxide to hemoglobin results in the formation of carboxyhemoglobin. Carbon monoxide has a higher affinity for hemoglobin than oxygen and decreases the hemoglobin’s ability to deliver oxygen to the tissues producing ischemia.

The normal range for percent carboxyhemoglobin for adults is 0.1% to 0.9% of total hemoglobin. When hemolytic disease is present with increased breakdown of hemoglobin, the carboxyhemoglobin levels can increase to approximately 2%. Values at this level can have adverse clinical effects in patients with preexisting heart disease. There is a poor correlation between carboxyhemoglobin levels and clinical findings. Table 6–11 shows the relative consequences of various amounts of carboxyhemoglobin, but individual patients demonstrate considerable variability in clinical symptoms. Children are much more susceptible to acute carbon monoxide poisoning and have a different clinical picture that mimics gastroenteritis. Like adults, they can also have serious neurologic sequelae and myocardial ischemia. Patients are often unaware of their exposure to carbon monoxide because it is odorless and nonirritating. There is no pathognomonic feature of carbon monoxide intoxication. A rapid diagnosis of carbon monoxide poisoning is important in order to institute appropriate management and identify sources of carbon monoxide before other exposures can occur.

### Diagnosis

Laboratory monitoring of carbon monoxide poisoning is performed by measurement of the carboxyhemoglobin levels. The patient also must be evaluated for possible underlying cause(s) of an increased carbon monoxide level (<10%), such as the presence of anemia, infection, and smoking that can increase carboxyhemoglobin levels. Because carbon monoxide

**Laboratory monitoring of carbon monoxide poisoning** is performed by measurement of the carboxyhemoglobin levels.
Toxicology can cause ischemic damage to skeletal and cardiac muscle, evaluation of ischemic muscle damage may also be appropriate.

**Lead**

**Description**

Lead poisoning is primarily a disease of childhood. As research has increased about lead toxicity, the threshold for defining lead poisoning has decreased over the past 20 years. Prior to 1970, lead poisoning (plumbism) was defined by blood levels greater than 60 \( \mu \text{g/dL} \). In 1971, the threshold was lowered to 40 \( \mu \text{g/dL} \). By 1975, the acceptable level was 25 \( \mu \text{g/dL} \) and since 1985, blood levels of 10 to 15 \( \mu \text{g/dL} \) have been recognized to impair cognitive and behavioral development. Most recently, the Centers for Disease Control and Prevention have adopted recommended lead levels in children of \(< 5 \mu \text{g/dL} \). As recently as 1992, 17.2% of children in the United States between the ages of 6 months and 5 years were estimated to have a blood lead level in excess of 15 \( \mu \text{g/dL} \), although this pales in comparison to those observed in developing countries. These children were primarily from low-income families in large urban settings. The sources of lead for these children included not only lead paint but also lead-contaminated household dust, soil, and workplace clothing; the use of lead-containing cookware; exposure to lead in storage batteries, in fishing and curtain weights; and even lead-contaminated water from the use of lead-soldered pipes in older buildings. Some canned food has been reported to contain lead. Lead-containing costume jewelry, medicines, and cosmetics (such as surma or kohl) imported to the United States from other countries have been demonstrated to contain lead. Obviously, the investigation of lead poisoning cases is important to identify the precise source of lead ingestion so that exposure can be eliminated.

There is a significant effort nationally to screen children, particularly those between the ages of 6 months and 5 years who live in, or are frequent visitors to, deteriorated housing built prior to 1960. Exposure to lead at high doses can produce persistent seizures, mental retardation, and chronic behavioral dysfunction. Most of the absorbed lead is stored in the bones. However, lead can also be found in soft tissues and erythrocytes. Lead interferes with the enzymes involved in heme synthesis, so lead exposure can lead to anemia. Renal toxicity is also observed in some cases of chronic lead poisoning. Any child with developmental delay, behavioral disorders, seizures, learning disabilities, iron deficiency, hearing impairment, renal disorders, and recurrent vomiting and abdominal pain should be considered for lead toxicity.

**Diagnosis**

A whole blood lead level reflects the lead burden of the body. For small children, a finger-stick sample is usually sent for analysis. Table 6–13 describes the laboratory monitoring for children suspected of lead poisoning relative to the presenting blood lead level. If the blood lead level is greater than 5 \( \mu \text{g/dL} \), testing of a sample taken by venipuncture is recommended to rule out skin contamination. If this “clean” specimen contains more than 5 \( \mu \text{g/dL} \) lead, parental education on possible exposure sources is recommended. While initial testing is often performed by anodic stripping voltammetry, confirmation testing especially for concentrations above 40 \( \mu \text{g/dL} \) is generally performed by atomic absorption or mass spectrometry. Free erythrocyte protoporphyrin (zinc protoporphyrin) is formed from heme synthesis as a result of lead toxicity. The measurement of free erythrocyte protoporphyrin is, however, an insensitive screening test for lead exposure because it does not detect lead poisoning in children with lead levels between 10 and 25 \( \mu \text{g/dL} \), and identifies less than 50% of children with blood levels greater than 25 \( \mu \text{g/dL} \). The utility of free protoporphyrin measurement is primarily to detect ongoing lead exposure. Because the anemia from lead poisoning may resemble iron deficiency anemia, studies for iron deficiency (such as serum ferritin and the red cell distribution width in the complete blood count) should be obtained to differentiate anemia of lead poisoning from iron deficiency anemia.

As understanding has increased about the toxicity of lead, the threshold for the definition of lead poisoning has decreased over the past 20 years.

A whole blood lead level reflects the lead burden of the body. For small children, a finger-stick sample is usually sent for analysis. If the blood lead level is greater than 5 \( \mu \text{g/dL} \), testing of a sample taken by venipuncture is recommended to rule out skin contamination.

The following actions are not recommended at any blood lead level: searching for gingival lead lines; testing of neurophysiologic function; evaluation of renal function (except during chelation with EDTA); testing of hair, teeth, or fingernails for lead; radiographic imaging of long bones; x-ray fluorescence of long bones. For adults, it is recognized that accumulation of lead occurs, and blood lead concentrations <25 μg/dL do not require action.

### REFERENCES

LEARNING OBJECTIVES

1. Identify the clinical testing of situations that indicate the need for prenatal testing of mother and/or infant, and the clinical consequences of premature birth.

2. Understand the rationale for selection of laboratory tests in neonatal screening programs.

3. Learn the assessment for diagnosis of Down syndrome and the clinical situations in which it is most often performed.

4. Learn the underlying defects that produce hemolytic disease of the newborn and cystic fibrosis and the laboratory test abnormalities associated with these disorders.

5. Learn the names of the diseases and the associated biochemical defects for the more commonly encountered or better characterized inborn errors of metabolism in the following categories:
   - Amino acidurias not involving urea cycle enzymes
   - Amino acidurias involving urea cycle enzymes
   - Lysosomal storage diseases with impaired degradation of sphingolipids
   - Lysosomal storage diseases with impaired degradation of mucopolysaccharides
   - Lysosomal storage diseases with impaired degradation of glycogen

INTRODUCTION

It is difficult to precisely identify the diseases of infancy and childhood because many disorders that begin in childhood become clinically evident in adulthood if a long period of time is required to generate a pathologic lesion. The topics chosen for inclusion in this chapter are disorders presenting almost exclusively in childhood. However, they obviously represent only a small fraction of “childhood disorders.” Many disorders in other sections of this book, such as hemophilia and numerous infections, occur or are diagnosed primarily in childhood. The chapter begins with an overview of prenatal and neonatal laboratory testing.

PRENATAL AND NEONATAL LABORATORY TESTING

Prenatal Testing and Screening

The disorders that can be diagnosed before birth number in the thousands. In families in which there is a history of a particular disorder, it is not uncommon to test prenatally for that particular disorder, often with DNA-based diagnostic tests. However, for the vast majority of families without a history of a specific illness, prenatal screening may also be undertaken. A screen differs from a test in that it does not provide a definitive diagnosis but rather an assessment of the risk of a diagnosis. For most of these families, screening is preferred as an initial step because it is less invasive; for example, there are several maternal serum screening assays (see below) for fetal Down syndrome (also known as trisomy 21), but testing for fetal Down syndrome requires an invasive procedure such as chorionic villus sampling or collection of amniotic fluid. The decision to screen is a personal one for families and includes considerations such as parental age and desire to avoid having a diseased child.

Neonatal Screening

Neonatal screening was originally developed to detect diseases such as phenylketonuria (PKU) and congenital hypothyroidism, for which early detection and intervention could prevent catastrophic consequences such as intellectual disability (mental retardation). Improvements in assay methodology, such as decreases in cost and the availability of tandem mass spectrometry for single assay detection of many abnormalities, have expanded the neonatal screening menu to include assays for diseases that are not preventable but are often treatable. All 50 US states screen for over 26 disorders, including amino acidurias (such as PKU and maple syrup urine disease), organic acidemias (such as isovaleric acidemia), fatty acid disorders (such as medium-chain acyl-CoA dehydrogenase [MCAD] deficiency), hemoglobinopathies associated with hemoglobin S, congenital hypothyroidism, congenital adrenal hyperplasia, cystic fibrosis, and classical galactosemia, among others. As new methods and new assays are developed, some variation between states’ neonatal screening menus will inevitably continue to exist; these variations are tracked on a Web site maintained by the National Newborn Screening & Global Resource Center.

As with any screening program, positive results require follow-up confirmation testing; false-positives do occur. Suggested actions and algorithms for neonatal screen positives are published on the Web by the American College of Medical Genetics and Genomics (ACMG). Urgent intervention is required for some of these disorders, to preserve life or prevent intellectual disability.

Neonatal Testing

The laboratory evaluation of an infant who appears clinically well in the first 24 hours of life but develops signs of illness on the second or third day may include:

- Blood gases to detect metabolic acidosis/alkalosis
- Urinalysis to detect ketonuria
- Complete blood count to detect abnormalities in blood cells
- A blood glucose test to detect hypoglycemia
A blood ammonia test to detect elevated ammonia
Liver function tests to detect hepatic dysfunction
Prothrombin time and partial thromboplastin time to detect coagulopathies
Blood lactate to detect lactic acidosis

Table 7–1 lists a number of screening laboratory tests that are typically ordered when there is suspicion that a neonate (or older child) is suffering from an inborn error of metabolism. The results of these tests only suggest specific disorders, with additional testing required to identify a specific metabolic defect. Definitive tests to make a conclusive diagnosis of a metabolic disorder often involve the measurement of specific enzyme activities or various metabolites in a pathway. Because sepsis is often suspected, it must be ruled out in the sick infant if there are any signs or symptoms of infection.

PREMATURITY

Description
A major cause of neonatal mortality and morbidity is prematurity, defined as birth prior to 37 weeks of gestation. When preterm labor or premature rupture of membranes causes prematurity, the underlying etiology is not often apparent, although it is believed to be commonly associated with infection or inflammation. Maternal correlates of prematurity include diabetes, obesity, intervention for infertility, genital or urinary infection, periodontal disease, low socioeconomic status, and other factors. Conflicting information exists about the value of intervention such as use of antibiotics for infection or infection risk.

Another cause of prematurity is iatrogenic, when the medical condition of the mother and/or fetus compels intervention to produce early delivery. The timing of such elective intervention for early delivery is influenced by the risk for fetal organ immaturity. Principal among these concerns is lung immaturity that is associated with the development of respiratory distress syndrome in the newborn.

Diagnosis
Risk of preterm delivery can be assessed by measurement of fetal fibronectin in cervical or vaginal fluid. This glycoprotein is produced by fetal membranes and appears in the cervix and vagina early in pregnancy as implantation develops, but normally disappears by week 20. Its reappearance in the third trimester often precedes labor and delivery. Its chief clinical value lies in its negative

CSF, cerebrospinal fluid.
predictive value, that is, patients thought to be at risk for preterm labor who are negative for fetal fibronectin in their cervicovaginal fluid are very unlikely to deliver within 1 week of the laboratory result. The major barrier to the widespread use of the fetal fibronectin test, when positive, is that clinical interventions to end preterm labor are only partially successful.

In those instances when fetal or maternal health dictates early delivery, there are several tests available to assess fetal lung maturity. A simple and inexpensive test is to count lamellar bodies in amniotic fluid, using the platelet channel in a conventional hematology automated analyzer. These lamellar bodies are surfactant-containing products of Type II pneumocytes. The finding of greater than 50,000 lamellar bodies per microliter of amniotic fluid predicts lung maturity. If fewer bodies are present, further testing on the amniotic fluid sample is warranted. Other tests include identification of the presence of phosphatidylglycerol (PG), and determination of the ratio of lecithin to sphingomyelin (L/S ratio). (See Chapter 14 for additional information.)

**DOWN SYNDROME**

**Description**

Down syndrome is the most commonly encountered, clinically significant autosomal chromosome aberration affecting individuals beyond infancy. This genetic defect, which can be detected by cytogenetic analysis, is trisomy 21. More than 90% of Down cases occur as a result of meiotic nondisjunction. Down syndrome is characterized by intellectual disability, cardiac malformations, malformations of the digestive tract, eyes, and ears, and the development of an Alzheimer-like disease process in later life.

The overall birth prevalence of Down syndrome is approximately 1 in 1000 births. However, a woman’s individual risk to deliver an infant with Down syndrome depends substantially on her age. The risk increases significantly past age 35 years, with an incidence in the range of 1:270 to 1:100 by age 40 years.

**Screening and Diagnosis**

The neonatal diagnosis of Down syndrome is clinical, with metaphase chromosome analysis on peripheral blood serving merely to confirm the diagnosis.

Noninvasive fetal screening for Down syndrome involves many more tests (Table 7–2) that are used in combination to develop a risk assessment of Down syndrome during pregnancy. Definitive diagnosis of fetal Down syndrome during pregnancy is established by an invasive test, namely, metaphase analysis of cells from either chorionic villus sampling (typically limited to first trimester) or amniotic fluid collection. The decision to engage in fetal screening for Down syndrome or to move from screening tests to invasive diagnostic testing once a risk assessment is completed depends on patient preference. The invasive tests to assess for Down syndrome during pregnancy do carry a risk of miscarriage.

First-trimester screening typically consists of measurement of 2 analytes in maternal serum: pregnancy-associated plasma protein A (PAPP-A) and the free beta subunit of human chorionic gonadotropin (fβhCG); the former is low and the latter high in mothers carrying a Down syndrome fetus. A third part of first-trimester screening is ultrasound assessment for nuchal translucency, which is increased as a result of fluid accumulation in the neck of a Down syndrome fetus. This first-trimester screening is associated with a sensitivity of approximately 85%, with a 5% false-positive rate. Nuchal translucency alone is not recommended in singleton pregnancy because its sensitivity is only about 70%. However, in multiple gestation pregnancies, the interpretation of maternal serum markers can be problematic, while the nuchal translucency test permits evaluation of each fetus. Determination of nuchal translucency is highly operator-dependent and requires specific training.

Second-trimester screening typically consists of the so-called quadruple screen of maternal serum, consisting of measurement of the following analytes: alpha-fetoprotein, unconjugated estriol (both decreased in mothers carrying a Down syndrome fetus), and total hCG and inhibin A (both increased in such mothers). The quadruple screen has a detection rate of approximately 81% with a 5% false-positive rate. An older test, the “triple screen” includes all of these second-trimester markers except inhibin A. It is characterized by higher false-positive rates and lower
detection rates. Maternal serum results are typically described in the form of “multiples of the median” (or MoM); the normal range is highly dependent on several factors including gestational age, number of gestations, maternal weight, and race.

Combining first- and second-trimester screens can provide an even higher level of detection. One approach is to sequentially conduct the tests; that is, inform the patient of the results of the first-trimester screen as soon as they are available (this permits her to choose a more definitive diagnostic method if indicated), and later perform the quadruple screen in the second trimester if appropriate. A noninvasive test that rivals the sensitivity and specificity of invasive testing is DNA sequencing of circulating cell-free fetal DNA (ccffDNA) in maternal serum. This test could also identify other chromosome aneuploidy syndromes such as trisomy 18 and trisomy 13. Current recommendations for follow-up of positive ccffDNA sequencing results are to confirm the abnormality by invasive testing (metaphase analysis on chorionic villus or amniotic fluid samples), but a negative ccffDNA sequencing test in a patient whose first- or second-trimester screen is positive for Down syndrome may provide an option to forgo invasive testing.

A final point about maternal serum screening is that the alpha-fetoprotein assay in the quadruple screen, if elevated, provides a measure of increased risk for neural tube defects such as spina bifida. These cases can be further studied by amniotic fluid collection, with assessment of acetylcholinesterase as well as alpha-fetoprotein (both elevated with neural tube defects) and high-resolution ultrasound examination.

### INFECTIOUS DISEASES IN THE PERINATAL PERIOD

**Description**

A number of maternal infections affect the fetus and newborn. Bacterial vaginosis, sexually transmitted diseases, and others increase the risk of preterm labor. Rubella and syphilis are associated with congenital anomalies. Neonatal death has been linked to a number of infections, including cytomegalovirus (CMV), group B streptococcus, herpes simplex, *Listeria*, parvovirus, and others. Postnatal disease in the offspring occurs with many infections, such as hepatitis B and C, human immunodeficiency disease (HIV), CMV, rubella, toxoplasmosis, and syphilis.
Screening and Diagnosis
Routine prenatal care is designed to screen for several of these infections, for the purpose of identifying pregnant women who need intervention or identifying susceptibility for a poor outcome in the mother. The results of maternal screening tests may have implications for the fetus, especially when they indicate maternal infection during pregnancy. An example of the latter is rubella serology screening of maternal serum. Routine testing includes serologic testing for syphilis, hepatitis B and C, and HIV. Routine rectovaginal culture for group B streptococcus is performed late in the third trimester. Detection through nucleic acid testing and/or culture is carried out for *Chlamydia* and for gonorrhea in high-risk mothers, and for herpes simplex in mothers with genital lesions.

HEMOLYTIC DISEASE OF THE NEWBORN

Description
Hemolytic disease of the newborn (HDN), also known as erythroblastosis fetalis, is a syndrome in which the newborn becomes anemic from the destruction of his/her RBCs in utero. This RBC destruction is a result of maternal IgG antibodies formed against a red cell antigen, most commonly the Rh antigen (also known as D antigen), which are then delivered into the fetal circulation across the placenta. Antibody production by a mother who is Rh-negative results from exposure to Rh-positive fetal cells during pregnancy and, to a much greater extent, at delivery. Therefore, the women at greatest risk for delivering infants with HDN are Rh-negative mothers who conceive Rh-positive babies, and are in the second or subsequent pregnancies. It is general practice to identify risk of sensitization during pregnancy and treat the mother prophylactically by rapidly removing Rh-positive fetal cells through passive immunization with Rh immune globulin. Such immunizations are almost always effective in preventing the mother’s immune system from developing these alloantibodies. Treatment is employed not only following delivery, when fetal to maternal bleeding is expected, but also during pregnancy itself.

Other red cell alloantibodies may be involved, although much less commonly. A form of HDN, usually mild, results from transplacental passage of IgG-class antibodies against A or B red cell antigens, to a Type A, B, or AB fetus. This disorder may occur with the first pregnancy, as it involves maternal antibodies that normally arise without the requirement of a previous pregnancy or incompatible blood transfusion.

Neonatal disease related to maternal antibody may occasionally involve targets other than RBC antigens; examples include neonatal alloimmune thrombocytopenic purpura (NAIT) with maternal antiplatelet antibodies.

Screening and Diagnosis
ABO/Rh typing is used in routine prenatal care to identify the mother’s blood type. An antibody screen against a standard panel of red cells, employing the indirect antiglobulin method (see Chapter 2), is also routinely performed to determine if there are maternal alloantibodies (such as anti-Rh) that might be a threat to the fetus.

Testing for fetal blood type (which establishes presence or absence of fetal susceptibility in that pregnancy), as well as monitoring for fetal anemia and hyperbilirubinemia (the latter a consequence of the RBC destruction), typically requires invasive procedures such as amniocentesis (withdrawal of amniotic fluid) or cordocentesis (withdrawal of blood from the cord, in utero). Both of these carry some risk of pregnancy loss or fetal damage. A new, noninvasive approach is possible with genetic testing for the antigen genes. Genotyping of the father that reveals homozygosity of the antigen gene implies fetal antigen positivity. Heterozygosity in the father implies a 50% chance of fetal antigen negativity, in which case there would be absence of risk for HDN. Confirmation of fetal antigen negativity can be accomplished by genotyping of fetal DNA that is present in maternal plasma. Titering the quantity of maternal antibody as a disease predictor in the fetus has been used, but the amount of antibody does not always correlate with the severity of the disease. Testing of amniotic fluid for bilirubin by spectrophotometric analysis can be performed to help manage the disease; fetuses at high risk of severe anemia, based on the amniotic fluid bilirubin, would be delivered if tests of fetal lung maturity on the amniotic fluid sample (see above) reveal a low risk of
respiratory distress syndrome. Otherwise, intrauterine blood transfusion and exchange could be performed. A noninvasive ultrasound test can detect fetal middle cerebral artery flow rates that correlate well with the presence of fetal anemia. This test has been shown to be more sensitive, specific, and accurate than the invasive amniotic fluid bilirubin measurement.

Laboratory evaluation of newborns for HDN includes complete blood count and direct anti-globulin test (DAT) on cord blood. The latter test detects the presence of immunoglobulin and/or complement deposited on the surface of red blood cells. See Table 7–3 for a list of tests that are helpful in the laboratory evaluation of HDN.

### CYSTIC FIBROSIS

**Description**

Cystic fibrosis is an autosomal recessive disease that results from a mutation in the cystic fibrosis transmembrane conductance regulator (CFTR) gene on the long arm of chromosome 7. The clinical presentation is dysfunction of exocrine glands, from abnormal chloride conduction across the apical membrane of epithelial cells, and subsequently chronic obstructive lung disease and exocrine pancreatic insufficiency. The most commonly found mutation in the CFTR gene is ΔF508 (loss of a phenylalanine codon at position 508), and it is present in approximately 70% of cases. However, more than 1800 mutations in this gene have been described, most of which are rare and some of which are equivocally associated with disease.
The incidence of cystic fibrosis is approximately 1 in 2500 to 3400 Caucasian births, 1 in 17,000 births from individuals of African descent, and 1 in 90,000 Asian births. As many as 1 in 29 Caucasians may be a carrier for cystic fibrosis.

**Screening and Diagnosis**

Extending an offer to screen the carrier status of couples planning for pregnancy is now recommended, especially for Caucasians (who are at highest risk) and those with a family history of disease. The carrier screen is a molecular genetic test designed to detect the most common mutations, typically around 23 in number.

Screening newborns for the disease is increasingly common. The usual approach is to screen blood spots for immunoreactive trypsinogen (IRT) and then follow up elevated values with either a multiple-mutation DNA test or repeat IRT on a new sample.

Laboratory evaluation for screen-positive patients includes the same test used in the assessment of patients clinically suspected of having the disease: quantitative sweat chloride. This analysis involves testing to determine whether the patient exhibits elevated levels of chloride in sweat samples; these samples are typically elicited with the use of pilocarpine and iontophoresis.

Genetic testing for disease detection (as opposed to screening) involves a larger number of mutation investigations, typically more than 75. If necessary, nucleotide sequencing of the gene can be performed; this procedure would typically be limited to the proband within a family; if an unusual mutation is found, other family members can be tested with sequencing of DNA from the involved exon rather than the entire gene.

Five classes of gene mutations, each specific for a different type of CFTR malfunction, have been described. The development of CFTR-modulating drugs, specific for a particular class of mutations, makes the genetic characterization of CF all the more important. Table 7–4 presents the laboratory evaluation of cystic fibrosis.

**AMINO ACIDURIAS**

**Description and Diagnosis**

Amino acidurias are defects in the metabolism of amino acids that lead to their accumulation. The primary amino acidurias are a result of an inherited enzyme defect within a degradative pathway for a specific amino acid, or in a transporter in the renal tubules, that alters the reabsorption of the amino acid.
acids or by finding the associated abnormality in the gene coding for the enzyme. The presence of characteristic clinical signs and symptoms for the individual disorders is highly contributory toward establishing a diagnosis. The different amino acidurias vary from essentially benign, with no apparent disease, to lethal disorders. Furthermore, the clinical features can vary widely within a single disease, because some of the amino acidurias have multiple forms and because some enzyme deficiencies can result in an elevation of the same amino acid.

**LYSOSOMAL STORAGE DISEASES**

**Description and Diagnosis**

Lysosomal storage diseases, like the amino acidurias, are inborn errors of metabolism. The lysosomal storage diseases result from the lysosomal accumulation of compounds that should otherwise be degraded by the enzymes in the lysosome. The diagnosis of a lysosomal storage disease is made by identifying the products stored in the tissues or excreted in the urine. Demonstration of an enzyme deficiency is usually sufficient for diagnosis of a specific lysosomal storage disease. With some disorders, DNA analysis for the mutation producing the enzyme deficiency also can be performed. As with the amino acidurias, a number of lysosomal storage disorders have subtypes,
CHAPTER 7  Diseases of Infancy and Childhood

because different enzyme deficiencies may result in the accumulation of similar or identical compounds. Table 7–6 provides a list of selected lysosomal storage disorders grouped into those associated with impaired degradation of sphingolipids (the sphingolipidoses), mucopolysaccharides (the mucopolysaccharidoses—the more recently invoked term for mucopolysaccharide is glycosaminoglycan), and glycogen. Among the lysosomal storage diseases, Tay–Sachs, one of the sphingolipidoses, has been the most thoroughly studied. As a class of disorders, the lysosomal storage disorders are rare. The one with the highest prevalence is Gaucher disease, which affects 1 in 600 in the Ashkenazi Jewish population. Each lysosomal storage disorder has its own characteristic clinical features, and most signs and symptoms of these diseases are expressed early in life. Many of these disorders can even be diagnosed in utero or in the period immediately after birth. There is often an urgency to establish the diagnosis so that appropriate treatment can be instituted as soon as possible.

### Neuroblastoma

**Description**

Neuroblastoma is a solid tumor that affects infants and toddlers. It is the most common malignancy under 1 year of age, and most patients are diagnosed by age 2 years. It presents either as a mass, often in the abdomen or neck, or with signs and symptoms of tumor spread, including bone
pain or spinal cord dysfunction. Neuroblastoma is one of the “small round cell” tumors of childhood, and it must be distinguished from other tumors of that type, which include lymphoma, rhabdomyosarcoma, Ewing sarcoma, and primitive neuroectodermal tumor (PNET).

**Diagnosis**

Measurement of urinary catecholamines can be used to alert clinicians to the likelihood that an infant’s tumor mass is a neuroblastoma, as the other “round cell tumors” listed above do not excrete catecholamines. Unlike pheochromocytoma (see Chapter 22), urinary metanephrines are not helpful, as neuroblastomas do not produce an abundance of epinephrine. For the diagnosis and monitoring of neuroblastoma, vanillylmandelic acid (VMA) and homovanillic acid (HVA) are typically measured in urine by high-performance liquid chromatography (HPLC) methodology.

The treatment of neuroblastoma patients can be followed with quantitation of VMA and HVA in their urine. Detection of metastases in bone marrow samples of these patients is challenging with histologic methods as there are often very few tumor cells, but molecular studies are now being used to detect minimal residual disease. Examples of such assays being used for this purpose include reverse transcriptase-polymerase chain reaction (RT-PCR) for tyrosine hydroxylase (an enzyme involved in catecholamine synthesis) and for the proto-oncogene MYCN. The latter gene is of interest because its copy number in neuroblastoma tumor samples has prognostic significance. Amplification of MYCN is associated with a poorer prognosis in these patients. There is interest in developing other biomarkers for neuroblastoma; chromogranin A and neuron-specific enolase are 2, among several, in use or in development.

LEARNING OBJECTIVES

1. Identify the lipid and nonlipid laboratory assays useful in the evaluation for cardiovascular risk and describe how they are used in conjunction with other information.

2. Learn the names of the most commonly encountered or best characterized primary hyperlipidemias, their associated serum or plasma lipid abnormalities, and the defects responsible for the initiation of the disorders.

3. Learn the correctable causes of hypertension that can be identified by laboratory tests.

4. Understand the different forms of vasculitis and the role of antineutrophil cytoplasmic antibodies (ANCA) in their diagnosis.

5. Learn the role of plasma D-dimer concentration and radiographic studies in the diagnosis of deep vein thrombosis.

CHAPTER OUTLINE

Introduction 197
Atherosclerosis 198
Hypertension 203
Vasculitis 204
Deep Vein Thrombosis and Pulmonary Embolism 206

INTRODUCTION

Because blood vessels are present in all organs and tissues, vascular disease is not restricted to a limited group of signs and symptoms. All organs and tissues are potential targets of injury in vascular disease, and most patients present with signs and symptoms indicative of injury to a specific organ or tissue, usually as a result of diminished blood flow. For example, if there is decreased blood flow to the heart, the patient presents with signs and symptoms related to cardiac dysfunction. The decrease in blood flow could be the result of a lesion that originates in the blood vessel wall, and therefore a vascular disease, or an obstruction by a blood clot inside the blood vessel. The disorders originating within the blood vessel wall include atherosclerotic vascular disease, hypertensive vascular disease, vasculitis, tumors, and aneurysms. Blood vessel disorders that may result from an abnormality that is not within the blood vessel wall include deep vein thrombosis (DVT), and what the DVT may generate if any of the clot moves to the lungs, pulmonary embolism (PE). DVT and PE are also discussed in this chapter. A first-time DVT or PE is nearly always the result of clot formation inside a normal vein. However, if an abnormality in vein anatomy exists, such as congenital atresia of the inferior vena cava, such defects within the blood vessels themselves can be highly contributory to the development of a DVT.
• Atherosclerotic vascular disease is one of the most predominant illnesses in the Western world. The goal of clinical laboratory testing is to identify the cause of atherosclerosis. This is usually related to excess dietary lipid or a disorder of lipid metabolism. This chapter provides information on disorders of lipid metabolism that lead to atherosclerosis.

• Hypertensive vascular disease is also common. The role of clinical laboratory testing is to determine if there is a correctable cause for hypertension. Because more than 90% of hypertension cases are “essential,” there is currently no correctable cause. Treatment with antihypertensive medical therapy is important and beneficial, but it does not treat the underlying cause for hypertension in most cases. Some causes of hypertension, however, are identifiable and correctable, often surgically. An example of a surgically correctable form of hypertension is one in which a tumor secretes a hormone responsible for the elevation of blood pressure. Removal of the tumor typically results in normalization of the blood pressure. The section “Hypertension” focuses on the correctable causes of hypertension and the laboratory tests useful in identifying them.

• Vasculitis represents a less commonly encountered group of disorders with inflammation in the blood vessel wall. Clinical laboratory testing has a limited role in establishing the diagnosis of a particular form of vasculitis. The diagnosis is made by the specific clinical features of the patient, the results of antineutrophil cytoplasmic antibody (ANCA) testing for some forms of vasculitis, and, on occasion, histopathologic review of a blood vessel biopsy specimen.

• DVT and PE are primarily diagnosed with imaging studies. However, an important test in the clinical laboratory, used primarily to rule out DVT and PE when the result is negative, is the D-dimer test.

**ATHEROSCLEROSIS**

**Description**

Atherosclerotic vascular disease is a major cause of mortality and morbidity in the Western world. It is the consequence of an accumulation of lipid in large arteries including the aorta and, thereby, a narrowing of the lumen of the arteries, which results in decreased blood flow. When an atherosclerotic plaque ruptures, a thrombus can form over the ruptured plaque and totally occlude blood flow. Atherosclerotic disease is vascular in origin in that lipid deposition and cell proliferation occur within the blood vessel wall. The end-organ damage depends on the anatomic location of the occluded artery. It is common to have generalized atherosclerosis with multiple vascular beds affected.

The causes of atherosclerotic vascular disease include:

• Ingestion of excess or atherogenic dietary fat, which is primarily saturated fatty acids and cholesterol. This is the most common cause of atherosclerotic vascular disease.

• Primary lipid disorders, also known as primary hyperlipidemias, which result in an increase in cholesterol, triglyceride, or both in the plasma. Many of these disorders are a result of genetic mutations that perturb the metabolism of cholesterol. They are not uncommon.

• Nonlipid disorders causing elevations in the concentration of plasma lipids, usually cholesterol and/or triglyceride. These are called secondary hyperlipidemias. Disorders or conditions that adversely affect lipid metabolism include hypothyroidism, nephrotic syndrome, liver disease, diabetes, obesity, and alcohol abuse. In addition, many medications can alter plasma lipid levels.

• Though not common, elevated levels of lipoprotein(a) (Lp(a) and pronounced “L-P-little a”) with or without other lipid or lipoprotein abnormalities.

• Also not common, disorders that are associated with direct damage to the blood vessel wall, such as high circulating concentrations of homocysteine.

**Diagnosis**

The initial approach to the patient for routine evaluation or for monitoring the status of atherosclerotic vascular disease is to determine if the patient has an elevation in serum or plasma total cholesterol and LDL cholesterol concentrations, and a low HDL cholesterol concentration, and if so, to first determine if the likely cause is excess intake of dietary fat.
An elevated total cholesterol level (>200 mg/dL) prompts the need to determine the plasma or serum concentrations of low-density lipoprotein (LDL) cholesterol (a high level is bad) and high-density lipoprotein (HDL) cholesterol (a high level is good). Table 8–1 describes the lipoproteins that transport lipids in the plasma.

Late in 2013, the American College of Cardiology and the American Heart Association, in conjunction with the National Heart, Lung, and Blood Institute, developed new guidelines. These contained substantial changes from the previous guidelines that were established more than a decade earlier by the Adult Treatment Panel III (ATP III). Previous targets for LDL cholesterol of 100 mg/dL, with the optional goal of less than 70 mg/dL, were removed as indicators of treatment success. Instead, 4 treatment groups for statin therapy have been identified. They are individuals with clinical atherosclerotic vascular disease; those with LDL cholesterol levels greater than 190 mg/dL; those with diabetes between 40 and 75 years old with LDL cholesterol levels between 70 and 189 mg/dL without evidence of atherosclerotic vascular disease; and individuals without evidence of cardiovascular disease or diabetes who have LDL cholesterol levels between 70 and 180 mg/dL and a 10-year risk of atherosclerotic vascular disease greater than 7.5%. The risk for stroke has been added to the coronary events traditionally covered by cardiovascular risk assessments. Specific recommendations on lifestyle for cardiovascular disease prevention include eating a diet rich in fruits, vegetables, whole grains, fish, low-fat dairy, lean poultry, nuts, legumes, non-tropical vegetable oils with restriction of saturated fats, trans fats, sweets, sugar sweetened beverages, and sodium; and engaging in aerobic physical activity of moderate to vigorous intensity lasting 40 minutes per session 3 to 4 times per week. With regard to weight loss, the new recommendation is that patients with a BMI of 25, not 30 as in the past, who have even one comorbidity, such as an elevated waist circumference, should begin treatment for weight loss.

**LDL Cholesterol**

The most common method for determining LDL cholesterol is a calculation that requires the use of a fasting sample with a triglyceride level less than 400 mg/dL. The LDL is calculated according to the Friedewald formula, which is: calculated LDL cholesterol = total cholesterol − HDL cholesterol − (triglycerides/5). The very-low-density lipoprotein (VLDL) fraction is represented by (triglycerides/5) with the assumption that there is very little triglyceride in LDL and HDL. Because the plasma and serum triglyceride concentration increases with ingestion of dietary fat, a fasting sample is required for an accurate calculation of LDL cholesterol using the Friedewald formula. Although it is acceptable to drink water, the patient may not ingest any calories 8 to 12 hours before the blood sample is collected. If the patient does not fast, and the triglyceride is elevated above baseline, the calculated LDL cholesterol will be falsely low. Another challenge to an accurate determination of LDL cholesterol is that there is substantial biological variability,
independent of any change in dietary habits, in the total cholesterol level. This would also have a
significant impact on the calculated LDL value. For that reason, testing for total cholesterol and
LDL cholesterol should be repeated on a second sample drawn 1 to 8 weeks later. The mean value
from these 2 samples is used, as long as the differences between them are less than 30 mg/dL in
total cholesterol. If the difference is greater than 30, a third sample should be obtained and the
mean of the 3 samples calculated. The day-to-day variability in total cholesterol within a single
individual is typically at least 10% and can be as high as 30%. This level of variability, in a patient
whose LDL cholesterol is calculated using the Friedewald formula, could span a range of values
from 125 to 165 mg/dL if the patient has a true value of 145 mg/dL. The Friedewald calculation
fails if the triglyceride concentration in the fasting sample is higher than 400 mg/dL. At such high
concentrations, the (triglyceride concentration/5) is no longer a reasonable estimate of the VLDL
cholesterol concentration.

Assays that directly measure LDL are also available. These are not dependent on the Friedewald
formula, and therefore independent of the triglyceride concentration. For that reason, fasting is
not required if a direct LDL assay is performed. The direct LDL cholesterol assay circumvents the
issues associated with the calculated LDL cholesterol when it is greater than 400 mg/dL. However,
even though these assays are routinely used, some studies have shown substantial imprecision
with the assay, although this conclusion has been challenged by other studies. In addition, direct
LDL cholesterol measurement is not useful in patients with a dyslipidemia.

**HDL Cholesterol**

Low levels of HDL cholesterol (<40 mg/dL) represent a cardiac risk factor. However, an elevated
HDL cholesterol concentration greater than or equal to 60 mg/dL reduces cardiovascular risk, and
if present, it allows subtraction of 1 risk factor from the sum of the risk factors. The patient does
not need to fast prior to sample collection for performance of the HDL cholesterol.

**Total Cholesterol**

The total cholesterol concentration is the sum of HDL cholesterol, LDL cholesterol, VLDL
cholesterol, intermediate-density lipoprotein cholesterol (IDL cholesterol), and cholesterol
associated with LP(a). In the vast majority of patients, the cholesterol in IDL and in LP(a) is very
small relative to the other lipoproteins. The patient does not need to fast prior to sample collection
for performance of the total cholesterol. Like HDL cholesterol, total cholesterol is not affected by
recent dietary intake.

**Non-high-density Lipoprotein Cholesterol**

Non-HDL cholesterol is the difference between the total cholesterol concentration and the
HDL cholesterol concentration. The remaining lipoprotein particles—LDL, VLDL, IDL, and
LP(a)—are all atherogenic. In some clinical trials, non-HDL cholesterol was shown to be
superior over LDL cholesterol as a measurement of cardiovascular risk. Because neither the
total cholesterol nor the HDL cholesterol is affected by the triglyceride level or ingestion of
dietary fat, non-HDL cholesterol can be calculated on nonfasting specimens. Use of non-HDL
cholesterol measurements instead of calculated LDL cholesterol measurements avoids the
problem of calculating LDL cholesterol in patients who have triglyceride concentrations greater
than 400 mg/dL.

**High-sensitivity C-reactive Protein**

The level of persistent inflammatory processes relates to the risk of cardiovascular events. Patients
who have an existing inflammatory process typically have CRP levels greater than 3.0 mg/L.
Transient elevations in CRP associated with benign processes occur frequently, and for that reason
repeat testing within 2 weeks of an elevated value is recommended to determine if the CRP level
exceeds 3.0 mg/L. The American Heart Association and the National Cholesterol Education Panel
concur that CRP levels should be measured only after traditional lipid parameters have been
assessed completely, with the CRP levels used to classify only those patients who are considered
to have borderline cardiovascular risk. Values for CRP of less than 1.0 mg/L represent low risk;
1.0 to 3.0 mg/L is intermediate cardiovascular risk; in patients with greater than 3.0 mg/L CRP
is considered to be at high cardiovascular risk. The CRP assay was not originally designed for a high-sensitivity analysis, and previously was only used to measure much higher values than the levels used in cardiovascular risk assessment.

**Tests Not Included for Cardiovascular Risk by the 2010 American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines for Asymptomatic Individuals**

Homocysteine, LP(a) (primarily because of lack of standardized assays), fibrinogen (although immunoassays appear to provide better predictive data than functional clot-based assays), apolipoproteins (even though low apo A-I levels, associated with HDL, and high apo B-100 levels, associated with LDL, are found in patients with increased cardiac risk, neither parameter adds information beyond what is provided by HDL cholesterol and LDL cholesterol), lipoprotein particle size, lipoprotein density, natriuretic peptides, and genomic testing.

**Metabolic Syndrome**

Metabolic syndrome is present when a series of risk factors for developing heart attack stroke and diabetes are present. In the United States, metabolic syndrome is extremely common, affecting more than 40% of people above the age of 60. Patients with the metabolic syndrome do not have physical symptoms. However, patients who have the metabolic syndrome, over time, commonly develop atherosclerotic vascular disease (myocardial infarction and stroke), kidney dysfunction, and type 2 diabetes with its associated risks and complications. Different expert groups have established the risk factors and their levels that are part of the metabolic syndrome from the American Heart Association and the National Cholesterol Educational Program.

- **Waistline**: For men, greater than 40 in; for women, greater than 35 in
- **Elevated triglycerides**: Equal to or greater than 150 mg/dL
- **Reduced HDL cholesterol**: For men, less than 40 mg/dL; for women, less than 50 mg/dL
- **Elevated blood pressure**: Equal to or greater than 130/85 mm Hg or use of a medication for hypertension
- **Elevated fasting glucose**: Equal to or greater than 100 mg/dL or use of a medication for hyperglycemia

**Assessment of Cardiovascular Risk**

Patients for whom testing for lipid status and inflammation is most useful include those with factors that increase cardiovascular risk, such as cigarette smoking, hypertension, diabetes mellitus, obesity, physical inactivity, or a family history of coronary heart disease, who are currently asymptomatic and have no history of coronary heart disease. As noted below in the scoring calculations for cardiovascular risk, decisions about patient management involve an assessment for both non-laboratory-test- and laboratory test-associated risk factors. There are a number of risk calculations based on a combination of data from clinical history, signs and symptoms, and laboratory test results. The following are risk scores and their associated parameters. Collectively, they represent a risk for developing atherosclerotic plaques and to a much lesser extent, with inflammatory markers included, the risk of plaque rupture.

- **The Framingham score**: total cholesterol, HDL cholesterol, age, gender, smoking status, and blood pressure.
- **The Reynolds score**: high-sensitivity C-reactive protein (hs-CRP), total cholesterol, HDL cholesterol, age, gender, parental history, smoking status, and blood pressure. In women with diabetes, the hemoglobin A1C result is also included.
- **The PROCAM score**: LDL cholesterol, HDL cholesterol, triglycerides, family history of coronary artery disease, smoking status, age, and presence of diabetes. This score is validated only in men.
- **Systematic coronary risk evaluation (SCORE)**: total cholesterol, HDL cholesterol, age, gender, smoking status, and blood pressure.
Genetic Disorders Classified by Causation of an Excess or Deficiency of a Specific Class of Lipoprotein

Genetic abnormalities are much less common explanations for high blood lipid levels than excess intake of dietary fat.

- **LDL-associated abnormalities:**
  
  Familial hypercholesterolemia: Defects in the LDL receptor gene cause an accumulation of LDL particles in the plasma. Patients have an elevated plasma LDL cholesterol and premature coronary artery disease.
  
  Familial defective apolipoprotein B: The defective apolipoprotein B has a reduced affinity for the LDL receptor. Affected individuals usually have an elevated LDL cholesterol, but there is wide variability in the LDL cholesterol levels.
  
  Hypobetalipoproteinemia: Hypobetalipoproteinemia results from a mutation within the apolipoprotein B gene that results in truncation of the mature apolipoprotein B. This condition is not associated with an increased risk of cardiovascular disease.
  
  Abetalipoproteinemia: This condition is caused by mutation in a gene coding for a protein required for assembly of apolipoprotein B-containing lipoproteins in the plasma. Affected patients suffer from mental and developmental retardation as children.

- **Triglyceride-rich lipoprotein (VLDL and chylomicrons [CM]-associated) abnormalities:**
  
  Familial hypertriglyceridemia: This disorder is highly heterogeneous and likely results from several genetic defects with a strong environmental influence. Plasma triglycerides and VLDL cholesterol are moderately to markedly elevated. There is not a strong relationship with coronary artery disease.
  
  Familial hyperchylomicronemia: These patients have severe hypertriglyceridemia with associated complications such as pancreatitis, xerostomia, and xerophthalmia. The hypertriglyceridemia results from either a markedly reduced or absent level of lipoprotein lipase activity or, less commonly, the absence of the activator of this enzyme, which is apolipoprotein C-II.
  
  Type III hyperlipoproteinemia: This disorder is characterized by an accumulation in the plasma of remnant lipoprotein particles, mostly from CM and VLDL. The excess plasma lipoprotein results in pathognomonic tuberous xanthomas and palmar striated xanthomas.
  
  Familial combined hyperlipidemia: This is a common familial lipoprotein disorder strongly associated with coronary artery disease. The disorder appears to result from hepatic overproduction of apolipoprotein B-containing glycoproteins, delayed clearance of triglyceride-rich lipoprotein, and increased flux of free fatty acids to the liver. There is genetic heterogeneity among patients with this disorder and considerable overlap exists between this disorder and metabolic syndrome.

- **HDL-associated abnormalities:**
  
  Apolipoprotein A-I gene defects: Defects in genes for apolipoprotein A-I, C-III, and A-IV can all decrease the production of HDL particles. Some of these defects are associated with premature cardiovascular disease. However, other mutations appear to confer longevity despite very low HDL levels.
  
  Lecithin cholesterol acyltransferase (LCAT) deficiency: A deficiency of LCAT results in reduced conversion of cholesterol to cholesterol esters in the plasma. This results in low HDL cholesterol levels, corneal opacities, and hemolytic anemia.
  
  Cholesterol ester transfer protein (CETP) deficiency: Patients with this deficiency have extremely elevated HDL cholesterol levels, which are primarily cholesterol esters. A deficiency of this enzyme causes accumulation of cholesterol esters within the HDL particles, and, therefore, this deficiency is not associated with premature coronary artery disease.
  
  Tangier disease: Individuals with this disorder have reduced cellular cholesterol efflux. The mutation is in the gene that codes for the protein known as ATP-binding cassette A1 (ABCA1), which is a transporter protein. Many different mutations within this gene
have been associated with Tangier disease, which is associated with an increased risk for coronary artery disease and extremely low HDL levels.

Familial HDL deficiency: These patients have low HDL cholesterol levels and are at increased risk for coronary artery disease. This is more common than Tangier disease and also appears to result from mutations in the ABCA1 gene.

**HYPERTENSION**

**Description**

Hypertension is a very common chronic disease, particularly in Western countries. In the United States, approximately 1 in 3 adults suffers from hypertension, but most of these individuals have no identifiable cause for their hypertension. A number of clinical practice guidelines have been published that provide a definition of hypertension. Although there is some variability, a normal systolic blood pressure is between 120 and 129 mm Hg, and a normal diastolic blood pressure is between 80 and 84 mm Hg. Systolic blood pressures between 130 and 139 and diastolic blood pressures between 85 and 89 are considered high normal by most guidelines; mild hypertension is systolic blood pressures of 140 to 159 and diastolic blood pressures of 90 to 99; systolic blood pressures of 160 to 179 or diastolic blood pressures of 100 to 109 represent moderate hypertension; and severe hypertension is defined as systolic blood pressure greater than 180 or diastolic blood pressure greater than 110. (The 2013 reference by Al-Ansary et al is a systematic review of the recent clinical practice guidelines on the diagnosis, assessment, and management of hypertension.)

In evaluating a patient with hypertension, 1 question is whether there is an identifiable cause for the hypertension or whether it is idiopathic or "essential." Another important question is whether the hypertension has resulted in damage to the organs commonly injured in hypertensive individuals, namely, the brain, the heart, and the kidneys.

Hypertension with a potentially correctable cause is suggested by certain symptoms, such as flushing and sweating (which are associated with pheochromocytoma), findings on physical examination such as a renal bruit (which is associated with renal artery stenosis), and laboratory abnormalities such as hypokalemia, which can be found in patients with hyperaldosteronism. Among children, up to 85% with hypertension have a secondary cause and, therefore, require a careful evaluation of the patient for correctable cause. In children up to the age of 18 years, coarctation of the aorta and renal parenchymal disease are common etiologies for hypertension. Among adults, 5% to 10% for patients with hypertension have a secondary cause. Young adults with secondary hypertension are often explained by abnormalities in thyroid function and fibromuscular dysplasia. In middle-age adults, the most common secondary cause of hypertension is hyperaldosteronism. In older adults, atherosclerotic renal artery stenosis, renal failure, and hypothyroidism predominate as secondary causes. There are many drugs causative for an elevation in blood pressure in some patients. Notable ones include oral contraceptives, selected nonsteroidal anti-inflammatory drugs such as ibuprofen, a variety of drugs used to treat psychiatric disorders such as tricyclic antidepressants, steroids such as methylprednisolone, and many herbal medicines and illicit drugs.

To understand the causes of hypertension, it is necessary to understand the mechanism by which blood pressure is regulated (see Chapter 22 for a related discussion on adrenal gland hormones). In response to decreased arterial pressure from a variety of causes, there is decreased blood flow to the kidney, causing the kidney to secrete renin. Renin released within the renal circulation converts angiotensinogen to angiotensin I, which is subsequently converted to angiotensin II. This molecule acts on the adrenal cortex to release aldosterone. Aldosterone increases sodium retention by the kidney, and thereby expands the extracellular fluid volume and returns the blood pressure to normal. Any alteration in this pathway, such as an increase in aldosterone or a decrease in blood flow to the kidney, will activate the renin–angiotensin system, lead to inappropriate fluid accumulation, and increase the blood pressure. This is why many of the diseases producing hypertension listed in Table 8–2 are associated with kidney dysfunction. The renal disorders that are associated with hypertension can be renovascular, in which case the blood flow to the kidney is decreased, or they can be parenchymal. Parenchymal diseases include chronic kidney infections, glomerulonephritis, and polycystic kidney disease, among many others. Most of these conditions are treatable, and treatment of the underlying disorder may reduce the hypertension. Abnormalities in the adrenal gland, such as a pheochromocytoma...
or an aldosterone-secreting tumor (discussed in Chapter 22), also can lead to hypertension, and may be surgically correctable.

**Diagnosis**

The hypertensive patient undergoing evaluation is first studied using a number of routine tests including:

- Complete blood count to determine if the patient is anemic or polycythemic.
- Electrolyte measurements to measure the potassium and bicarbonate levels.
- Creatinine concentration in plasma or serum and creatinine clearance to assess renal function.
- Glucose (usually a fasting level) to diagnose diabetes, because diabetic patients have an approximately 2-fold higher incidence of hypertension than nondiabetic patients.
- Urinalysis to detect the presence of diabetes by glucose in the urine; urinalysis also may indicate the presence of significant parenchymal disease in the kidney if proteinuria, hematuria, or pyuria is present.

The tests to further investigate the cause of hypertension beyond the screening tests are more invasive, costly, or esoteric. These are noted in Table 8–2.

**VASCULITIS**

**Description**

The systemic vasculitides are disorders in which there is inflammation of the blood vessels and tissue necrosis. The different forms of vasculitis are classified by the size of the vessels affected. The classification of the different forms of vasculitis remains controversial and suboptimal, largely

BUN, blood urea nitrogen.
because of the low prevalence of these diseases, which are anatomically, epidemiologically, and clinically distinct. Vasculitis is known as primary vasculitis when there is no identifiable underlying etiology. Secondary vasculitis represents vasculitides in which there is an underlying condition. The underlying condition may be an infection such as HIV, or hepatitis B or hepatitis C, or an underlying connective tissue disease such as lupus or rheumatoid arthritis. The basis for identifying a specific form of vasculitis is histopathologic examination of the blood vessel, but this is often not feasible because of the blood vessels involved and the danger of obtaining tissue from them. It is for this reason that the classification must rely on criteria other than histopathology.

The large number of different vasculitides, which are sometimes overlapping in their clinical or anatomic characteristics, often makes the diagnosis of a specific form of vasculitis challenging. In general, a diagnosis is made by 1) the presence of characteristic clinical findings for the particular form of vasculitis and 2) inflammation within a specific size of blood vessels, as shown in Table 8–3. There are vasculitides that are infectious in origin that are not included in Table 8–3. Rocky Mountain spotted fever, syphilis, aspergillosis, herpes, and neisserial infections can all be associated with vasculitis. (See Chapter 5 for information on organisms and infections that can cause vasculitis.)

**Diagnosis**

The laboratory testing is different for each of the vasculitides listed in Table 8–3. ANCA are autoantibodies, typically IgG, directed against antigens in neutrophils (most commonly) and monocytes. Because they are detected in patients with some forms of systemic vasculitis, known as the ANCA-associated vasculitides, they have been used diagnostically to identify patients with these particular forms of systemic vasculitis. These include Wegener’s granulomatosis, microscopic

ANCA, antineutrophil cytoplasmic antibody; BUN, blood urea nitrogen.
polyangiitis, and Churg–Strauss syndrome as shown in Table 8–3. Immunofluorescence on ethanol-fixed neutrophils helps to differentiate the different ANCA patterns. Although there are subtypes, the principal forms of staining are p-ANCA (which is perinuclear staining), c-ANCA (which is cytoplasmic staining), and atypical ANCA. The most common target of p-ANCA antibodies is myeloperoxidase, a neutrophil granule protein involved in the generation of oxygen radicals. Less commonly these antibodies will recognize lactoferrin, elastase, and cathepsin G. The c-ANCA antigen is specifically proteinase 3 (PR3).

Some of the vasculitides will affect the kidney, and for those, monitoring of renal function is important. The diagnosis of a particular form of vasculitis can be supported by a variety of other test results.

**DEEP VEIN THROMBOSIS AND PULMONARY EMBOLISM**

**Description**

DVT and PE are common disorders. The major concern for patients with DVT is the risk of embolism to the lungs (PE). The presence of a thrombosis in a deep vein in the leg is a risk factor for PE, but a thrombosis in a superficial vein in the leg is not. Clots in the superficial veins cannot embolize to the lungs. A DVT in the leg that is above the knee presents a significantly greater risk for PE than does a thrombosis in a deep vein that is below the knee. If the DVT has extended above the knee, patients are more likely to experience soft tissue swelling and discomfort, distention of the vein (a palpable “cord” on physical examination), Homans sign (pain on dorsiflexion of foot), erythema, and warmth. Upper extremity (usually arm) DVTs are much less common than lower extremity (leg) DVTs. A lower extremity DVT, especially if it is small, is often asymptomatic. Thrombosis in the pulmonary circulation can occur independently of DVT, but thrombosis in the pulmonary vasculature commonly results from thrombi originally developed in the deep veins of the leg.

Both DVT and PE are commonly associated with one or more congenital or acquired risk factors for thrombosis. The acquired factors include trauma, immobilization, the postoperative state, antiphospholipid antibodies, malignancy, myeloproliferative disorder, pregnancy, and the postpartum state, among many others. The most commonly encountered congenital risk factors, described in detail in the section “Hypercoagulable States” in Chapter 11, include the factor V Leiden mutation that produces activated protein C resistance, the prothrombin G20210A mutation, and deficiencies of protein C, protein S, and antithrombin.

**Diagnosis**

As a thrombus is degraded, degradation products of cross-linked fibrin are generated. One of these degradation products is the D-dimer. The D-dimer levels are typically elevated in patients with DVT and PE. However, the D-dimer level can be elevated in many other clinical conditions associated with fibrin formation and degradation. These include malignancy, trauma, disseminated intravascular coagulation, and the postoperative states. Because of this, the diagnostic strength of the D-dimer test is its effectiveness in ruling out DVT and PE, when the result is negative. The assays for D-dimer measurement involve the use of monoclonal antibodies that specifically recognize the D-dimer. There are many different clinical assays with different sensitivities and specificities, but despite the variability in available assays for D-dimer, there are now many that can be used effectively in ruling out thrombosis in patients who do not have a high clinical probability of DVT and PE.

Clinical decision rules have been useful in standardizing the evaluation of patients with suspected DVT or PE, before the determination of the D-dimer. One commonly used clinical decision rule is the Wells rule for DVT. Information from the medical history and physical examination are obtained, and points are assigned based on the presence of these individual parameters. For PE, 2 extensively validated clinical decision rules are the Wells rule and the revised Geneva score. These 2 decision rules vary in the items that are included in the evaluation and the number of points assigned when the individual parameters are present.

Imaging studies provide definitive diagnostic information in the evaluation of patients for DVT and for PE. In patients suspected of acute DVT, with a clinical decision rule score that makes DVT unlikely, the D-dimer test is performed first. If the test is negative, DVT is ruled out,
but if the test is positive, a compression ultrasonography study is performed. A positive compression ultrasonography test confirms the DVT, and a negative test rules out DVT. In patients who have an evaluation with clinical decision rules that makes a DVT likely, the compression ultrasound is performed before the D-dimer. A positive compression ultrasound confirms the DVT, but a negative compression ultrasound prompts the performance of the D-dimer. A negative D-dimer test rules out the DVT, but a positive D-dimer test prompts a repeat compression ultrasound in 1 week. Computed tomography (CT) scanning for DVT can be used to evaluate the patient with leg swelling and equivocal compression ultrasonography.

Patients suspected of acute PE but with an unlikely diagnosis by clinical decision rules are evaluated first with a D-dimer test, just like for DVT. A negative D-dimer rules out the PE, but a positive result leads to the performance of a CT pulmonary scan. This imaging study involves injection of intravenous contrast material. The presence of intraluminal filling defects in the pulmonary arteries confirms a diagnosis of PE. In patients suspected of acute PE whose clinical decision rule analysis suggests PE, the imaging study is performed without the D-dimer test, and the result of the imaging study determines whether the PE is present or absent.

There are a variety of other imaging studies that can be performed to evaluate patients for DVT or PE, but these are much less commonly used. PE is also discussed in Chapter 14.

Table 8–4 presents the imaging studies and the D-dimer tests and their use in the diagnosis of DVT and PE.

INTRODUCTION

There are many forms of cardiac disease. This chapter briefly covers the role of biomarkers in acute myocardial infarction (AMI) and congestive heart failure (CHF). The large numbers of other cardiac diseases are not discussed in this chapter because of the relatively minor role of diagnostic clinical laboratory tests in these disorders.

ACUTE MYOCARDIAL INFARCTION

Description

The term AMI is defined as an imbalance between myocardial oxygen supply (ischemia) and demand, resulting in injury to and the eventual death of myocytes. AMI should be used when there is evidence of myocardial necrosis in a clinical setting consistent with acute myocardial ischemia. Such necrosis is most often associated with a thrombotic occlusion superimposed on coronary atherosclerosis. It is now apparent that the process of plaque rupture and thrombosis is 1 of the ways in which coronary atherosclerosis progresses. Total loss of coronary blood flow
results in a clinical syndrome associated with an ST-segment elevation MI (STEMI). Partial loss of coronary perfusion, if severe, can lead to necrosis as well, which is generally less severe and is known as non-ST-segment elevation MI (NSTEMI). Both STEMI and NSTEMI are considered type 1 MIs. In instances of myocardial injury with necrosis with a condition other than coronary artery disease (CAD), which contributes to an imbalance between oxygen supply and/or demand (eg, coronary endothelial dysfunction, respiratory failure, hypotension, etc), this MI is a type 2 MI that is secondary to ischemic imbalance. Other ischemic events of lesser severity without myocardial necrosis are designated as angina, which can range from stable to unstable. About 1.7 million patients are hospitalized each year in the United States with an acute coronary syndrome (ACS). Approximately 700,000 patients suffer from an initial AMI annually and another 500,000 from a recurrent AMI. Coronary heart disease causes 20% of all deaths and cardiovascular diseases up to 40%. Historically, most deaths caused by ischemic heart disease have been acute, but as our therapeutic abilities have improved, the disease is slowly becoming a more chronic one.

In many patients with AMI, no precipitating factor can be identified. The clinical history remains of substantial value in establishing a diagnosis. A prodromal history of angina can be elicited in 40% to 50% of patients with AMI. Of the patients with AMI presenting with prodromal symptoms, approximately one third have had symptoms from 1 to 4 weeks before hospitalization; in the remaining two thirds, symptoms predate admission by a week or less, with one third having had symptoms for 24 hours or less. The pain of AMI is variable in intensity, and the discomfort is described as a squeezing, choking, vise-like, or heavy pain. It may also be characterized as a stabbing, knife-like, boring, or burning discomfort. Often the pain radiates down the left arm. In some instances, the pain of AMI may begin in the epigastrium and simulate a variety of abdominal disorders, which often causes AMI to be misdiagnosed as indigestion. In other patients, the discomfort of AMI radiates to the shoulders, upper extremities, neck, and jaw, again usually favoring the left side.

**Diagnosis**

The ideal biomarker of myocardial injury should 1) provide early detection of myocardial injury, 2) provide rapid, sensitive, and specific diagnosis for an AMI, 3) serve as a risk stratification tool in ACS patients, 4) assess the success of reperfusion after thrombolytic therapy, 5) detect reoclusion and reinfarction, 6) determine the timing of an infarction and infarct size, and 7) detect procedural-related perioperative MI during cardiac or noncardiac surgery. In reality, no 1 biomarker is able to 100% cover all these areas. However, cardiac troponin (cTn) does provide the power to be utilized in the majority of these clinical areas. Ruling in AMI requires a test with high diagnostic sensitivity (preferred by the ER physician in the urgent care, emergency setting as to not send anyone home with an AMI), whereas ruling out AMI requires a test with high diagnostic specificity (preferred by the cardiologist following admission to avoid excessive and costly diagnostic evaluations in the non-AMI patient). It is the function of the laboratory to provide advice to physicians about cardiac biomarker/troponin characteristics.

An updated 2012 “Global Task Force for the Third Universal Definition of MI” has codified the role of biomarkers. The advocate that the diagnosis be made from evidence of myocardial injury based on biomarkers of cardiac damage, preferably cardiac troponin (cTn) I or T, in the appropriate clinical situation of ischemic symptoms.
TABLE 9–1  Criteria for Diagnosis of Acute Myocardial Infarction

The term acute myocardial infarction (MI) should be used when there is evidence of myocardial necrosis in a clinical setting consistent with acute myocardial ischemia. Under these conditions any 1 of the following criteria meets the diagnosis for MI:

- Detection of a rise and/or fall of cardiac biomarker values (preferably cardiac troponin [cTn]) with at least 1 value above the 99th percentile upper reference limit (URL) and with at least 1 of the following:
  - Symptoms of ischemia
  - New or presumed new significant ST-segment T-wave (ST-T) changes or new left bundle branch block (LBBB)
  - Development of pathological Q waves in the ECG
  - Imaging evidence of new loss of viable myocardium or new regional wall motion abnormality
  - Identification of an intracoronary thrombus by angiography or autopsy

- Cardiac death with symptoms suggestive of myocardial ischemia and presumed new ischemic ECG changes or new LBBB, but death occurred before cardiac biomarkers were obtained, or before cardiac biomarker values would be increased

- Percutaneous coronary intervention (PCI)-related MI is arbitrarily defined by elevation of cTn values (>5 × 99th percentile URL) in patients with normal baseline values (≤99th percentile URL) or a rise of cTn values >20% if the baseline values are elevated and are stable or falling. In addition, i) symptoms suggestive of myocardial ischemia, ii) new ischemic ECG changes, iii) angiographic findings consistent with a procedural complication, or iv) imaging demonstration of new loss of viable myocardium or new regional wall motion abnormality are required

- Stent thrombosis associated with MI when detected by coronary angiography or autopsy in the setting of myocardial ischemia and with a rise and/or fall of cardiac biomarker values with at least 1 value above the 99th percentile URL

- Coronary artery bypass grafting (CABG)-related MI is arbitrarily defined by elevation of cardiac biomarker values (>10 × 99th percentile URL) in patients with normal baseline cTn values (≤99th percentile URL). In addition, i) new pathological Q waves or new LBBB, ii) angiographically documented new graft or new native coronary artery occlusion, or iii) imaging evidence of new loss of viable myocardium or new regional wall motion abnormality are required

Further, the universal classification of different types of myocardial infarction is highlighted in Table 9-3.

- **cTn testing** is most useful when patients are having nondiagnostic ECG tracings. Patients with AMI can be categorized into several groups based on time of presentation. First, there is the group of patients who present very early to the emergency department (ED), within 0 to 4 hours after the onset of ischemic symptoms that include chest pain, without diagnostic ECG evidence of AMI. For laboratory tests to be clinically useful, biomarkers (cTn) of MI must be released rapidly from the heart into the circulation to provide sensitive and tissue-specific diagnostic information. Further the analytical assays using serum, plasma, or whole blood specimens must be rapid and sensitive enough to distinguish small changes within the reference interval. The second group includes those presenting 4 to 48 hours after the onset of ischemic symptoms, without evidence of AMI on ECG. In this group, the diagnosis of AMI requires serial monitoring of both cTn and ECG changes. The third group presents more than 48 hours after the onset of symptoms of ischemia with nonspecific ECG changes. The ideal biomarker, again cTn, of myocardial injury in this group would persist in the circulation for several days to provide a late diagnostic time window. The shortfall of such a marker might be its inability to distinguish recurrent injury from old injury, thus the importance of following a rising or falling pattern. The fourth group includes those who present to the ED at any time after the onset of ischemic symptoms with clear ECG evidence of AMI, either a STEMI or Q-wave MI. In this group, detection with biomarkers of myocardial injury is theoretically not necessary.

**Cardiac Troponin**

The contractile proteins of the myofibril include the regulatory protein troponin. Troponin is a complex of 3 protein subunits, troponin C (the calcium-binding component), troponin I (the inhibitory component), and troponin T (the tropomyosin-binding component) (TIC). The subunits exist in isoforms distributed between cardiac muscle and slow and fast twitch skeletal muscle. Troponin is localized primarily in the myofibrils (94%–97%), with a smaller
cytoplasmic fraction (3%–6%). cTn subunits I and T have different amino acid sequences encoded by different genes allowing for their cardiac tissue specificity. Following myocardial injury, multiple forms are elaborated both in tissue and in blood. The multiple forms of cTnI include the T–I–C ternary complex, IC binary complex, and free I. Multiple chemical modifications of these 3 forms can occur, involving oxidation, reduction, phosphorylation and dephosphorylation, and both C- and N-terminal degradation. The conclusions from these observations are that cTn immunoassays need to be developed in which the antibodies recognize epitopes in the stable region of cTnI and, ideally, demonstrate an equimolar response to the different cTnI forms that circulate in the blood.

### Analytical Methods for Measuring Cardiac Troponin

Over the past 20 years, numerous manufacturers have developed monoclonal antibody-based diagnostic immunoassays for the sensitive measurement of cTnI and cTnT. Assay times range from 5 to 30 minutes. Table 9–4 shows analytical characteristics of representative assays approved by the FDA for patient testing. In clinical practice, 2 obstacles limit the ease for switching from 1 cTnI assay to another. First, there is currently no primary reference cTnI material available for manufacturers to use for standardizing assays. Second, concentrations fail to agree because of the different epitopes recognized by the multiple, different antibodies used in different assays. Therefore, standardization of cTnI assays remains elusive. For cTnT, there is only 1 manufacturer. Therefore, there are no standardization problems. In 2012, the IFCC Task Force on Clinical Applications of Cardiac Biomarkers readdressed quality specification aspects for cTn assays. These specifications were intended for use by the manufacturers of commercial assays and by clinical

laboratories using cTn assays to establish uniform criteria so that all assays could be evaluated objectively for their analytical qualities and clinical performance. Factors addressed included: antibody selection, calibration materials, imprecision characteristics at clinical decision values, effects of storage time and temperature, glass versus plastic tubes versus gel separator tubes, the influence of anticoagulants, and whole blood measurements.

99th Percentile Reference Value as a Cutoff for Diagnosis of Acute Myocardial Infarction

The Global Task Force’s 2012 “Third Universal Definition of Myocardial Infarction” guideline was predicated on cTn monitoring, with detection of a rising and/or falling cTn, and with at least 1 value above the 99th percentile value. Using the 99th percentile value (compared with the older WHO criteria) has demonstrated an increase in the number of MIs in day-to-day clinical practice, EDs, epidemiologic studies, and clinical trials. The data suggest that the more analytically sensitive cTn tests result in greater rates of MI diagnosis and greater rates of cTn positivity compared with the older biomarker CKMB. Milder and smaller MIs are detected. Clinical cases prior to 2007 that were earlier classified as unstable angina are given a diagnosis of MI because of an increased and rising cTn. Further, procedure-related troponin increases (ie, following angioplasty) will be labeled MI (Table 9–3). The importance of small troponin increases has been confirmed by their association with a poor prognosis.

Several biomarkers should no longer be used to evaluate cardiac disease. They include aspartate aminotransaminase (AST), total CK activity, CKMB isoforms, myoglobin, total lactate dehydrogenase (LD), and LD isoenzymes. These markers have poor specificity for the detection of cardiac injury because of their wide tissue distribution. Further, CKMB is no longer a recommended biomarker, and is suggested for clinical use only when cTn assays are not available. CKMB offers no additional diagnostic value to aid in the timing of the onset of myocardial injury, infarct sizing, or determination of reinfarction. There is no evidence to support dual testing for cTn and CKMB.

Role of Cardiac Troponin for Risk Outcomes Assessment

Patients With Ischemia

In the environment of preventive and evidence-based medicine, the use of cTnI or cTnT measured in patients with ischemia will allow clinicians to use biomarkers as both exclusionary and prognostic indicators. The results will assist in determining who is more at risk for AMI and death, and thereby determine who may benefit from early medical or surgical intervention. Such patients benefit from the use of anticoagulant therapy and the use of platelet antagonists, and an early invasive strategy. The goal of monitoring cardiac biomarkers in patients suggestive of ACS with and without AMI would be to effectively identify patients with unstable coronary disease and triage them to an appropriate therapeutic regimen. Optimal use of this strategy requires at least 2 blood samples for cTn measurement. General population screening of hospitalized patients with cTnI or cTnT is not recommended at present.

Patients With Nonischemic Presentations

Clinicians are often confronted with a clinical history of a patient without overt CAD and a low probability of myocardial ischemia. However, as a precautionary measure, serial cTns are ordered. A typical serial order set to rule in or rule out an AMI would include blood draws at 0 hour (presentation), 3, 6, and 9 to 12 hours. When 1 or 2 of the serial cTn concentrations are found to be increased, the clinician would likely be confronted with the following concerns: 1) What does the increase mean in the clinical setting of a nonischemic patient? 2) Is the increase a false-positive finding resulting from an analytical error? 3) Why was the test ordered in the first place? As cTn assays with increasing low-end analytical sensitivity (high-sensitivity [hs] cTn assays) have been developed (currently not FDA cleared for use in the United States), the ability to detect minor degrees of myocardial injury in a variety of clinical conditions has widened and has led to a better understanding that cTn is not just a biomarker for MI, but a sensitive biomarker for other cardiac conditions.
CHAPTER 9  The Heart  215

for myocardial injury. The 20% of suspected ACS patients who clinically do not rule in for MI, but display an increased cTn, represents patients with nonischemic pathologies (Table 9–2) in whom the mechanisms of injury are well defined (such as myocarditis, blunt chest trauma, and chemotherapeutic agents), and patients with increased cTn, in whom the mechanism of injury is not clear.

Orders for Serial Cardiac Troponin Testing

Blood samples should be drawn at presentation (0 hour) to the hospital (often this is hours after the index clinical symptom onset) and at least once more at 6 to 9 hours later. As noted, a typical serial order set to rule in or rule out an AMI would include blood draws at 0 hour (presentation), 3, 6, and 9 to 12 hours. Occasionally a patient may require a 12- to 24-hour sample, if the earlier measurements are normal, but the clinical suspicion of AMI is high. As the cTn concentration may remain increased 3 to 12 days after an AMI, after 2 positive values with a rising pattern, it does not appear cost-effective to continually monitor cTn once a diagnosis is established. In patients where recurrent MI is suspected from clinical signs or symptoms following the initial MI, an immediate remeasurement at the time of a suspicious new event (0) and 3-, 6-, and 9-hour serial blood samples are recommended. It is reasonable to suspect recurrent infarction if there is a >20% increase in the second value as long as it exceeds the 99th percentile.

High-sensitivity Cardiac Troponin Assays

It is important to understand that the term “high sensitivity” (hs) reflects the assay’s characteristics and does not refer to a difference in the form of cTn being measured. There is a need for a consensus on defining what nomenclature should be used for an hs assay. Several names have been used in the literature for these assays, but the term “high sensitivity” has been recommended by expert opinion. This term, however, begs the question: how does one define an hs assay? In a scorecard concept (Table 9–5), an assay is designated hs if it meets 2 basic criteria. First, the total imprecision (CV) at the 99th percentile value should be ≤10%. Second, measurable concentrations below the 99th percentile (the upper limit of normal) should be attainable with an assay at a concentration value above the assay’s limit of detection for at least 50% of healthy individuals. None of the current US-marketed assays for both central laboratory and point-of-care testing meet the 2-fold hs criteria. Concentrations for hs assays are expressed in nanograms per liter instead of the commonly published units of micrograms per liter.

For deriving normal reference 99th percentile cutoffs for cTn assays, it is recommended that inclusion criteria be based on data obtained from an interview for a history of medications and known underlying disease, as well as a blood measurement of a natriuretic peptide (NP; N-terminal pro–B-type natriuretic peptide [NT-proBNP] or B-type natriuretic peptide [BNP]), interpreted vis-à-vis a cutoff value for the exclusion of ventricular dysfunction to serve as a

surrogate biomarker for underlying myocardial dysfunction, and an estimated GFR to exclude renal disease. In addition, the groups should be split equally by sex and include a diverse racial and ethnic mix. Literature now supports reporting of gender-specific cutoffs for hs assays, as men demonstrate approximately 2-fold higher 99th percentiles compared with women.

With improved analytical sensitivity, hs assays have been shown to provide an earlier diagnosis, with the ability to rule in and rule out by 3 hours instead of 6 hours with contemporary assays. However, with increased clinical sensitivity, with the ability to detect smaller myocardial injuries from multiple, pathological etiologies, decreased clinical specificity, below 80%, occurs. Early studies have now demonstrated that the use of a delta change in cTn concentration over a 0- to 3-hour serial time window allows for the ability to separate acute injury, that is, AMI, from a chronic injury, such as heart failure, with improved clinical specificity up to 95%. This will be an important tool to use for clinical care when hs assays are cleared for use in the United States some time in 2014.

**CONGESTIVE HEART FAILURE**

**Description**

CHF is a condition in which there is ineffective pumping of the heart leading to an accumulation of fluid in the lungs. Typically, it results from a loss of cardiac tissue and subsequent function. It is defined as the pathophysiological condition in which an abnormality of cardiac function is responsible for the failure of the heart to pump sufficient blood to satisfy the requirements of the metabolizing tissues. In the United States, CHF is the only cardiovascular disease with an increasing incidence. The National Heart, Lung, and Blood Institute estimates that current prevalence is about 5 million Americans with CHF, with an incidence of approximately 400,000 new cases each year. CHF is the leading cause of hospitalization in individuals 65 years and older. Current prognosis is dependent on disease severity, but overall it is poor. The 5-year mortality is approximately 10% in mild CHF, 20% to 30% in moderate CHF, and up to 80% in end-stage disease.

**Diagnosis**

**Natriuretic Peptides in Monitoring CHF**

Two biomarkers have been well studied to assist in these clinical settings: B-type natriuretic peptide (BNP, pharmacologically active hormone) and N-terminal proBNP (NT-proBNP, not pharmacologically active peptide).

The ACC/AHA practice guidelines for the evaluation and management of CHF indicate that the role of NP in the identification of CHF patients remains to be clarified. In contrast, the ESC has incorporated monitoring NPs into their practice algorithm at the time of patient presentation alongside the clinical history, physical examination, ECG, and chest x-ray. An abnormal NP finding would trigger an echocardiogram or other imaging modality. NP concentrations in patients diagnosed with CHF are substantially increased (>1000 ng/L for BNP or >1800 NT-proBNP) when compared with patients who have minor increases (<300 ng/L) because of left ventricular (LV) dysfunction without acute CHF. CHF is more common in patients with advanced chronic renal disease. BNP and NT-proBNP are secreted in a pulsatile fashion from cardiac ventricles with an approximate half-life for BNP of 22 minutes in blood, with the NT-proBNP half-life on the order of 2 hours. While 1 mechanism of BNP clearance involves the renal parenchyma, the kidney is not thought to be the primary site for BNP clearance. The kidney more specifically affects NT-proBNP clearance. Thus, increases in BNP in hemodialysis patients are thought to represent both regulatory responses from the cardiac ventricle, resulting from increased wall tension, and a lack of renal clearance.
Importantly, NPs are not 100% specific for CHF. Increases have been described for other non-CHF etiologies involving filling pressure defects, including LV hypertrophy, inflammatory cardiac diseases, systemic arterial hypertension, pulmonary hypertension, acute and chronic renal failure, liver cirrhosis, and several endocrine disorders (eg, hyperaldosteronism and Cush-}

ing syndrome). In CHF patients presenting to the ED, patients admitted tend to have higher BNP concentrations (>500 ng/L) versus those who are discharged (mean <300 ng/L) at triage. Linear relationships with increasing BNP/NT-proBNP levels and the severity of CHF (NYHA classification I-IV) have been described. The largest prospective trial to date to evaluate the diagnostic value of BNP is “The Breathing Not Properly Multicenter Study,” from which the level of BNP was found to be an independent predictor of CHF. Using a blood BNP cutoff concentration of 100 ng/L for CHF, there was a 90% clinical sensitivity and 75% clinical specificity, with an 81% accuracy. Without BNP monitoring, clinical judgment and traditional diagnostic methods demonstrated a diagnostic accuracy of only 74%. The knowledge of BNP reduced the proportion of patients in whom the clinician was uncertain of the diagnosis from 43% to 11%. Plasma BNP monitoring in the ED improved the treatment and evaluation of patients with early dyspnea, reducing the time to discharge and total cost of treatment. Similar data have been shown for the alternate biomarker NT-proBNP. After an AMI, NP increases in proportion to the size of the infarction, prompting investigators to explore the role of screening BNP for detection of LV dysfunction. In post-MI patients, BNP concentrations are inversely correlated with LV ejection fraction. However, there is inconclusive evidence for the role of BNP screening for asymptomatic LV dysfunction in the general population. In general, there does not appear to be a distinct advantage to use 1 biomarker (BNP or NT-proBNP) over the other in clinical practice.

Blood NP monitoring can be valuable in the diagnostic setting, where it will possibly improve the performance of nonspecialist clinicians in diagnosing CHF. In clinical practice, NP monitoring can best be used as a “rule-out” test for suspected cases of new CHF. It is not a stand-alone test and should not be a replacement for a full clinical assessment, including an echocardiogram when indicated. In the presence of a normal BNP or NT-proBNP, a diagnosis of CHF is highly unlikely if concentrations are <100 ng/L for BNP or <300 ng/L for NT-proBNP. Monitoring NP may be useful in 1) guiding therapy, 2) monitoring the course of the disease, and 3) providing useful risk stratification information. NPs have been shown to be an independent predictor of cardiovascular mortality in patients with both CHF and ACS over a 1-year period. Further, BNP or NT-proBNP monitoring may assist in identifying patients with a lower risk of readmission within the next 30 days before discharge.

### Analytical Methods for Measuring Natriuretic Peptides

Table 9–6 shows the current FDA-approved assays for BNP or NT-proBNP. The commercial assays differ in standardization of measurements and antibodies used in the assay. Assays that use an antibody that recognizes the N-terminus labile region of BNP (eg, Biosite, Beckman, and Abbott) demonstrate less analyte stability at room temperature (24 hours) than assays that use 1 of their antibodies recognizing the C-terminus (eg, Siemens [Bayer]). The Roche NT-proBNP antibody configuration allows for 72 hours of sample stability at room temperature.

Reference Intervals: Medical Decision Cutoff Values

A number of clinical factors affect the BNP and NT-proBNP concentrations, most importantly age, gender, obesity, and renal function. Significant differences are observed between men and women (higher), and there are increasing concentrations with age by decade. For BNP and NT-proBNP, the significance of the results for these assays in relation to the degree of left ventricle dysfunction remains a debate. For both analytes, there is an inverse relationship between values and body mass index. For NT-proBNP, establishing reference intervals has been challenging. Review of both the FDA-approved US package insert and the European assay package insert reveals substantial differences in what concentrations are considered normal by age and sex. For BNP, a cutoff of 100 ng/L has been endorsed as demonstrating optimal sensitivity and specificity. For NT-proBNP, the FDA-approved package insert describes a 2-tier cutoff by age at <75 years: 125 ng/L and >75 years: 450 ng/L. However, more evidence-based cutoffs have been derived from the PRIDE/ICON studies based on age and renal function, and are recommended as follows—age <50 years: >450 ng/L; age ≥50 years: >900 ng/L; all ages: best negative predictive value <300 ng/L; age <50 years and eGFR >60 mL/min: 450 pg/mL, and eGFR ≤60 mL/min: 1800 ng/L; age ≥50 years and eGFR >60 mL/min: 900 pg/mL, and eGFR ≤60 mL/min: 1800 ng/L.

Implications for Therapy Using Test Results for Natriuretic Peptides

The utility of serial measurements of NPs in guiding therapy for chronic heart failure has been the subject of numerous randomized controlled trials reported in the literature since 2000. The existing trial data suggest that adjustment of treatment in chronic heart failure according to NP measurements, used in conjunction with established clinical treatments, is likely to reduce cardiac mortality and hospital admissions with heart failure, at least in patients with systolic heart failure who are younger than 75 years and relatively free of comorbidities.

Biological Variability

As BNP and NT-proBNP become more widely used to monitor CHF patients following therapy, questions have addressed the usefulness of serial monitoring in assisting the success of drug therapy. In a study of 11 patients with CHF, the biological variation for BNP and NT-proBNP was evaluated using 4 different assays. The findings indicated that a change of 130% for BNP and 90% for NT-proBNP is necessary before results of serially collected data can be considered clinically and statistically significant. For example, these findings imply that a decrease from approximately 500 to 250 ng/L would be necessary for a clinician to conclude that therapy was successful in improving CHF features. Clinicians without this knowledge may inappropriately assume that a decrease from an admission BNP value of 500 ng/L to a 24-hour post-admission value of 400 ng/L may have been a result of successful patient management. It has been suggested that following the admission BNP value, a second BNP value be obtained within 24 hours of discharge to optimize the diagnostic utility of BNP in the overall assessment of patients with CHF.

Novel Biomarkers for Heart Failure Risk Assessment

In addition to the advances in the understanding of established NP biomarkers in HF, there is an increased study of the elucidation of novel biomarkers potentially useful for the evaluation and management of patients with HF, and the growing understanding of important and relevant comorbidities in HF. Literature on candidate biomarkers from a number of classes will be growing over the next several years and include: a) myocyte stretch (with assays for ST2, GDF-15), b) myocyte necrosis (with hs-cTn assays), c) systemic inflammation (with assays for LP-PLA2), d) oxidative stress (with assays for MPO), e) extracellular matrix turnover (with assays for collagen propeptides), f) neurohormones (with assays for chromogranin A), and g) biomarkers of extracardiac processes, such as renal function (with assays for NGAL).

ANEMIA

Definition

Anemia refers to a deficiency in red blood cells (RBCs) and implies a decline in oxygen-carrying capacity. The complete blood count (CBC) provides several measures of red cell quantity, including RBC count, hemoglobin (Hb) concentration, and hematocrit (Hct) (see description of RBC indices later in this chapter). Hb concentration is the parameter most widely used to diagnose anemia, based on 1967 World Health Organization (WHO) recommendations (Table 10–1). This definition is not universally accepted, and numerous alternatives have been proposed over the years, usually suggesting slightly higher values and race-specific values. It is important to remember also that the normal ranges for Hb and Hct are different for infants, children, adult men, adult women, pregnant women, and the elderly. Attention to age- and gender-appropriate normal ranges is important in the evaluation of anemia.

Anemia may present with pallor, fatigue, dyspnea, or evidence of poor tissue oxygenation (chest pain due to poor cardiac oxygenation, altered mental status due to poor cerebral
Anemia stimulates several compensatory mechanisms. The cardiopulmonary system compensates by attempting to make the most of the blood it has by exchanging more gases (tachypnea), and circulating more volume (tachycardia). The marrow responds with increased erythropoiesis, stimulated by an increase in renal production of erythropoietin (EPO) in response to hypoxia. If the means to create mature red cells are intact (ie, if the underlying cause of the anemia is not a production or maturation defect), then this response can usually succeed. In addition to making more erythrocytes, the marrow begins to release immature erythrocytes into the circulation. Many of these still contain a network of ribosomes and rough endoplasmic reticulum involved in the making of Hb, which identifies them morphologically as reticulocytes (see description of reticulocyte counting later in this chapter). Over the next 3 to 4 days, this endoplasmic reticulum dissolves and a mature RBC results. In very brisk marrow responses, some red cells may be released that still contain a nucleus.

**Differential Diagnosis**

Identifying the cause of anemia is usually fairly straightforward. There are several strategies for reaching the diagnosis (Tables 10–2 and 10–3), 1 of which is illustrated in the algorithms (Figures 10–1 to 10–4). Examination of the peripheral smear is especially important, since numerous clues can be found there.

FIGURE 10–3  Diagnostic algorithm for macrocytic anemia.

**Normocytic anemia**

- **Reticulocyte count normal**
  - **Isolated anemia:**
    - Anemia of chronic disease
    - Early iron deficiency
    - Early folate/B₁₂ deficiency
    - Medication effect

  - **If all excluded:**
    - Pure red cell aplasia
    - Myelodysplasia
    - Paroxysmal nocturnal hemoglobinuria

- **Multiple cytopenias:**
  - Myelodysplasia
  - Bone marrow infiltration
  - Aplastic anemia

  - **Reticulocyte count increased**
    - No blood loss:
      - Probable hemolysis

**Macrocytic anemia**

- **Reticulocyte count low**
  - Hypersegmented neutrophils and MCV > 115:
    - Probable B₁₂ or folate deficiency

  - Low B₁₂ and folate confirms deficiency

- **Reticulocyte count high**
  - No hypersegmented neutrophils and MCV < 115:
    - Liver disease
    - Hypothyroidism
    - Down syndrome
    - Medication effect

  - All excluded

  - Macrocytosis due to reticulocytosis:
    - Anemia probably due to hemolysis or blood loss
    - Partially treated hypo-regenerative macrocytic anemia

  - Normal B₁₂ and folate

  - Probable myelodysplasia

**FIGURE 10–2**  Diagnostic algorithm for normocytic anemia.
Suspected hemolytic anemia (reticulocytosis, increased LDH):
Exclude splenic enlargement and occult bleed

Perform:
Peripheral smear
Bilirubin
Haptoglobin
Urine hemoglobin
Urine hemosiderin
Urine urobilinogen

Schistocytes
Bilirubin normal to increased
Haptoglobin decreased or absent
Urine hemoglobin positive
Hemosiderinuria present
Urobilinogen absent

Spherocytes, spur cells, bite cells, etc.
Bilirubin increased (especially indirect)
Haptoglobin normal to decreased
Urine hemoglobin absent
Hemosiderinuria absent
Urobilinogen increased

Intravascular hemolysis
Extravascular hemolysis

Microangiopathic: DIC, TTP, HUS, HELLP (clinical presentation)
Mechanical hemolysis, eg, heart valve (note history)
Toxins, eg, venoms (note history)
Infections, eg, malaria, babesia, clostridium (peripheral smear, history)
Oxidant stress, eg, some cases of G6PD deficiency (G6PD assay)
Hemolytic transfusion reaction, eg, ABO incompatibility (history)
Paroxysmal nocturnal hemoglobinuria (Ham’s test, flow cytometry)
Paroxysmal cold hemoglobinuria (detect anti-P antibody)

Membrane defects: eg, HS, HE (peripheral smear)
Pyruvate kinase deficiency (PK) (peripheral smear, PK assay)
Hemoglobinopathy (hemoglobin electrophoresis)
Thalassemia (red cell indices, hemoglobin electrophoresis)
Hemolytic transfusion reaction: eg, Rh, Duffy (history)
Oxidant stress, eg, some cases of G6PD deficiency (G6PD assay)

FIGURE 10–4 Diagnostic algorithm for suspected hemolytic anemia. DIC, disseminated intravascular coagulation; TTP, thrombotic thrombocytopenic purpura; HUS, hemolytic uremic syndrome; HELLP, hemolysis, elevated liver function tests, and low platelets; HS, hereditary spherocytosis; HE, hereditary elliptocytosis; G6PD, glucose-6-phosphate dehydrogenase.
to low reticulocyte count. Such hyporegenerative anemias include iron deficiency anemia, anemia of chronic disease (ACD), lead poisoning, folate deficiency, B₁₂ deficiency, myelodysplastic syndrome, aplastic anemia, and pure red cell aplasia.

Regardless of the morphology or red cell size, anemia that is accompanied by reticulocytosis suggests either hemolysis or hemorrhage. Some exceptions should be noted. One is a partially treated production defect, such as in the early treatment of iron, folate, or B₁₂ deficiency, in which one may find persistent anemia with reticulocytosis. Second, both hemolytic and blood-loss anemia may eventually lead to depletion of iron, folate, or B₁₂, and they can present as a production defect. Lastly, paroxysmal nocturnal hemoglobinuria (PNH) is a hemolytic anemia that may transform to aplastic anemia.

DIC, disseminated intravascular coagulation; TTP, thrombotic thrombocytopenic purpura; HUS, hemolytic uremic syndrome; HELLP, hemolysis, elevated liver function tests, and low platelets.

See Figures 10–5 to 10–18 for peripheral smears with abnormal red blood cell morphology.
Hemolytic anemias are those in which red cell survival, normally 120 days, is shortened. The premature destruction of erythrocytes may occur within the bloodstream (intravascular hemolysis) or within the reticuloendothelial system (eg, extravascular hemolysis). Intravascular hemolysis is caused by mechanical red cell trauma (microangiopathic hemolytic anemia [MHA] from mechanical heart valve), complement fixation on the red cell surface (eg, ABO incompatibility), paroxysmal nocturnal hemoglobinuria (PNH), paroxysmal cold hemoglobinuria (PCH), snake envenomation, and infectious agents (eg, malaria, babesiosis, Clostridium). Extravascular hemolysis is much more common and is typical for all remaining causes of hemolysis. The causes of hemolysis may be inherited or acquired. Inherited forms of hemolytic anemia usually, but not always, present in early childhood (Table 10–5).

Hemolytic anemia presents with jaundice, fatigue, tachycardia, and pallor. Enhanced excretion of Hb breakdown products often leads to the development of pigmented gallstones. Intravascular hemolysis may present with dark urine and back pain. Leg ulcers are common in sickle cell disease and hereditary spherocytosis (HS). Splenomegaly is a common finding in extravascular hemolysis. Laboratory findings in support of hemolysis include increased unconjugated bilirubin, increased lactate dehydrogenase (LD), and decreased haptoglobin. Reticulocytes, which are larger than mature red cells, are responsible for an unpredictability of the mean corpuscular volume (MCV). The blood smear may display helpful morphologic findings. Intravascular hemolysis is associated with hemoglobinuria and hemosiderinuria.

**Acute Blood Loss**

**Description**

Acute blood loss (hemorrhage) is seen most often as a result of surgery, trauma, or gastrointestinal pathology. Most often, hemorrhage is quite obviously present, but occasionally it is occult and internal (large retroperitoneal or pelvic hemorrhages). It can occur in the prehospital setting, and in that case its volume cannot be estimated.

The cardinal manifestations of acute blood loss—tachycardia, tachypnea, and hypotension—reflect not so much a decreased oxygen-carrying capacity as a decreased intravascular volume. A shift of water from the interstitial fluid compartment into the plasma leads to hemodilution and a lowered hematocrit (hct). It is for this reason that the initial treatment is intravenous fluid resuscitation with normal saline; only if this is unsuccessful is blood transfusion considered.

Chronic slow blood loss is generally well tolerated and usually presents late in the disease process as iron deficiency anemia. Acute blood loss is not the only form of anemia that can present abruptly. Causes other than hemorrhage that may present as rapid-onset severe anemia include intravascular hemolysis and acute exacerbations of a chronic compensated hemolytic anemia, such as in sickle cell disease (Table 10–6).

Diagnosis
The history and physical examination are the keys to arriving at the correct diagnosis. In perplexing situations, it may be necessary to exclude hemolysis. The main laboratory findings are a normocytic anemia with a marked reticulocytosis. The peripheral smear may be notable only for neutrophilia, a result of mobilization of granulocytes from marginal pools (demargination), which is a physiologic stress response. Somewhat later, there may be reactive thrombocytosis.

Iron Deficiency Anemia
Description
Within the cytoplasm of the marrow erythroblast, the predominant activity is the production of Hb molecules into which iron must be incorporated. Iron from the diet is absorbed principally in the duodenum. It is carried by transferrin to the marrow where it is internalized into erythroblasts and incorporated into protoporphyrin to yield heme. Iron not utilized in this way is stored bound to ferritin. When there is inadequate iron intake or excessive iron loss (Table 10–7), the ferritin–iron stores of the reticuloendothelial system become progressively depleted. Red cells are produced that contain an inadequate concentration of Hb, giving rise to the appearance of small, hypochromic red cells that are poorly equipped for the carriage of oxygen. Fewer mature red cells are subsequently produced, lowering the Hct (Table 10–8). The clinical manifestations include those directly attributable to anemia (fatigue, pallor), in addition to pica (a desire to ingest solids such as rock, dirt, or ice), atrophic glossitis, koilonychias, and esophageal webs. The coexistence of esophageal webs and iron deficiency has been called Plummer–Vinson syndrome. These latter manifestations are not commonly seen and follow prolonged, untreated iron deficiency.

Iron deficiency is the most common cause of anemia. Worldwide, the most common cause of iron deficiency is a dietary lack of iron. In the United States, iron intake is not usually problematic, although supply can lag demand in some populations, such as toddlers and pregnant women. The finding of iron deficiency produces an obligation to identify and treat the underlying cause. In American adults, this underlying cause is usually found within the gastrointestinal tract. Iron deficiency often is the first sign of an occult gastrointestinal malignancy.

</tr>
</tbody>
</table>

TIBC, total iron-binding capacity; RDW, red blood cell distribution width.
**Diagnosis**

In many cases, the CBC and peripheral blood findings are highly characteristic: low RBC count, low MCV, low mean corpuscular hemoglobin concentration (MCHC), and high red cell distribution width (RDW). The platelet count is often elevated. The peripheral blood shows hypochromic, microcytic red cells with scattered elliptocytes. This is in contrast to the most commonly entertained other diagnostic consideration, thalassemia, in which the RBC count is high, the RDW tends to be lower, elliptocytes are not seen, and target cells and basophilic stippling are more frequent.

To confirm the diagnosis of iron deficiency, the best single test is the serum ferritin. A ferritin above 15 μg/L essentially excludes iron deficiency, and the serum ferritin in iron deficiency is often below 10 μg/L. Lowered ferritin is the earliest finding in iron deficiency and persists throughout the course of the illness. The diagnostic difficulty with the use of ferritin is that it is an acute-phase reactant, an analyte that increases in response to inflammation. It may also be spuriously elevated in hepatic insufficiency, due to impaired clearance. Thus, other assays may occasionally be needed to make a diagnosis of iron deficiency anemia.

In established iron deficiency, the serum iron is typically low, the total iron-binding capacity (TIBC) is elevated, and the percent transferrin saturation is low. These findings are somewhat in contrast to those seen in anemia of chronic disease (see below). Serum soluble transferrin receptor is elevated whenever there are cells depleted of iron; thus, it is elevated in iron deficiency anemia and in erythroid hyperplasia (hemolytic anemia, polycythemia). Lastly, the zinc protoporphyrin (ZPP) and free erythrocyte protoporphyrin (FEP) are elevated in iron deficiency but also elevated in lead poisoning and anemia of chronic disease. As a last resort, marrow iron stores can be examined directly under the microscope if an adequate bone marrow aspirate is obtained.

**Anemia of Chronic Disease (ACD)**

**Definition**

Sustained systemic inflammation alters iron utilization in the marrow, suppresses hematopoiesis, and blunts the response of EPO to anemia. This combination of factors leads to a mild, refractory, hyporegenerative anemia that is usually normocytic and normochromic, but is microcytic in up to one third of cases. Although iron deficiency is the most common cause of anemia worldwide, ACD is the most common cause of anemia in both hospitalized and ambulatory hospital patients in the United States. The vast majority of cases are due to rheumatoid arthritis, collagen vascular disease such as lupus, chronic infection, and malignancy.

The means by which chronic inflammatory diseases cause anemia are still being elucidated. Marrow biopsies in patients with ACD display bountiful iron stores in the face of decreased iron uptake by erythroid precursors. Decreased transferrin receptors have been demonstrated on erythroblasts in ACD. In addition, patients with ACD have decreased production of EPO in response to anemia. Cytokines, including IFN-γ, TNFα, IL-1, and hepcidin, have been shown to produce the conditions of ACD when injected into laboratory animals.

**Diagnosis**

The diagnosis of ACD is made difficult by the presence of numerous comorbid factors, in patients who, by definition, are ill. In such patients, ACD may be coincident with iron deficiency, folate deficiency, renal insufficiency, and/or frequent phlebotomy. Furthermore, in up to 30% of those with iron indices characteristic of ACD, no chronic illness can be identified.

The laboratory diagnosis of ACD depends on demonstrating a hypoproliferative (low reticulocyte count) normocytic or microcytic anemia in the presence of characteristic iron studies. The iron studies should document increased iron stores (normal to high serum ferritin or increased stainable iron in a bone marrow biopsy) and a low serum iron, low transferrin, and low TIBC.

A normal or elevated ferritin level is crucial for distinguishing ACD from iron deficiency. However, interpretation of the results for ferritin can be problematic because ferritin is an acute-phase reactant. Thus, while a low ferritin is essentially diagnostic of iron deficiency, a normal ferritin does not entirely exclude it. In confusing situations, the soluble serum transferrin receptor assay may be helpful. This analyte is increased in iron deficiency anemia and normal in ACD.
Thalassemia

Description

Mutations in the genes that encode globin chains may result in 2 broad categories of disease. Some mutations lead to the production of a structurally abnormal globin chain, resulting in a hemoglobinopathy such as HbS (sickle cell disease and sickle cell trait). Other mutations lead to reduced production of a structurally normal globin chain, resulting in thalassemia.

A Hb molecule is composed of 4 polypeptide chains. The major adult Hb, hemoglobin A (HbA), is composed of 2 α chains and 2 β chains. The minor adult Hb (HbA2) is composed of 2 α chains and 2 δ chains. The major fetal hemoglobin (HbF) is composed of 2 α chains and 2 γ chains. The 1 constant feature of all Hbs is the α chain. The α chain genes are located on chromosome 16. Each chromosome 16 contains 2 separate α chain genes, for a total of 4 genes per normal cell, each transcriptionally active. Thus, to render an individual completely deficient of α chains, inheritance of 4 mutated genes is required. The β, γ, and δ chain genes are located on chromosome 11. Each chromosome 11 contains 1 β, 1 γ, and 1 δ gene. Should a mutation occur in the β chain, there can be a degree of compensation by increasing the production of γ, δ, or both. There is no such substitute for the α chain.

With decreased α chain production, α-thalassemia arises. Harm comes to the red cell, however, not from a deficiency of α chain, but from an excess of non-α chains (eg, β). The excess chains form precipitates in the cell, leading to ineffective erythropoiesis, microcytosis, and enhanced splenic red cell destruction. Likewise, decreased β chain production (β-thalassemia) leads to precipitation of excess α chains and subsequent red cell destruction. Disease severity reflects the genotype (Table 10–9).

Diagnosis

Since α chains are present in utero, α-thalassemia can be diagnosed at birth. The diagnosis of β-thalassemia is somewhat delayed, since β chains are not produced to adult levels until 3 to 6 months of age. The CBC is notable for microcytosis, usually in the presence of a normal or

high RBC count. The peripheral smear often displays target cells and may display basophilic stippling. When there is microcytosis, “thalassemic” indices, and normal iron studies, the diagnosis of thalassemia is essentially assured. In the case of β-thalassemia, a Hb electrophoresis displays increased HbA2 and sometimes HbF (see description of Hb electrophoresis later in this chapter and in Chapter 2). In α-thalassemia (recall that the α chain is needed for all Hb types), the proportion of hemoglobins appears normal. These findings are usually sufficient for the diagnosis. If further definition is required, molecular genetic testing is available.

**Folate Deficiency**

**Description**

Folate and vitamin B₁₂ deficiency (described next) are the classical causes of megaloblastic anemia. The term megaloblastic refers to the appearance of hematopoietic precursor cells in the marrow. Their nuclei appear abnormally large and immature, resulting from nuclear maturation that lags behind cytoplasmic maturation. This megaloblastic change affects not only erythroblasts but other rapidly dividing cells as well, including maturing granulocytes, megakaryocytes, and enterocytes. It results from impairment of DNA synthesis and has more than just morphologic consequences.

Erythropoiesis becomes ineffective, resulting in a hypercellular marrow. Many erythroblasts are destroyed while still in the marrow. Thus, megaloblastic anemia is in part a hemolytic anemia; indeed, intramedullary destruction of maturing erythrocytes leads to increased LDH and bilirubin, as one would associate with hemolytic anemia. The red cells that do proceed to maturity are macrocytic, with the MCV in fully developed megaloblastic anemia exceeding 115 fl.

Folate deficiency does not cause the same neurologic defect that vitamin B₁₂ deficiency causes. However, supplementation of folate in early pregnancy is known to reduce the incidence of neural tube defects. No clear mechanism for this effect has been established.

Dietary factors are a major cause of folate deficiency. Folate is found in leafy green vegetables, fruits, and legumes. Dietary folate is absorbed in the duodenum, and the body stores about a 4- to 5-month supply of it. Thus, within a relatively short time, poor diet, malabsorption, or excessive utilization can lead to folate deficiency (Table 10–10).

**Diagnosis**

The blood smear shows the classic features of megaloblastic anemia: marked oval macrocytosis, hypersegmented neutrophils, and large platelets. The diagnosis can be confirmed by measuring the serum or RBC folate. However, there are several confounding factors in the use of these tests. Several balanced meals can quickly normalize the serum folate, but the RBC folate reflects folate status better over time. Vitamin B₁₂ deficiency can produce a falsely low RBC folate, but it does not affect the serum folate.

**Vitamin B₁₂ Deficiency**

**Description**

Like folate deficiency, vitamin B₁₂ deficiency leads to megaloblastic anemia. The main difference between the 2 conditions is that B₁₂ deficiency may also produce a degenerative neurologic syndrome, the manifestations of which are attributable to demyelination of and loss of nerve fibers within the dorsal columns. The neurologic symptoms include paresthesia, weakness, and

<table>

</tr>
</tbody>
</table>

Folate and vitamin B₁₂ deficiency (described next) are the classical causes of megaloblastic anemia.
an unsteady gait. It is critical to make the diagnosis of B₁₂ deficiency and treat it appropriately, because these neurologic changes are not reversible.

Malabsorption is the major cause of vitamin B₁₂ deficiency (Table 10–11), most commonly from pernicious anemia. Pernicious anemia is a deficiency in gastric intrinsic factor (IF) due to an autoimmune assault on the gastric mucosa. Unlike folate deficiency, B₁₂ deficiency is rarely due to a poor diet. This is because 1) B₁₂ is abundant in a wide range of dietary sources and 2) the body stores several years worth of vitamin B₁₂. Dietary deficiency thus requires multiple years of a highly restrictive vegetarian diet.

### Diagnosis

The blood smear shows the classic features of megaloblastic anemia: marked oval macrocytosis, hypersegmented neutrophils, and large platelets. The diagnosis can be confirmed by measuring serum B₁₂ levels.

Identifying the cause of the deficiency is the next step in the evaluation. The Schilling test is designed for this purpose. The patient is given a parenteral dose of unlabeled B₁₂ followed by an oral dose of radiolabeled vitamin B₁₂. The purpose of the unlabeled dose is to fully saturate the body with B₁₂ so that the radiolabeled dose will be quickly excreted in the urine. A 24-hour urine sample is then collected. A low level of urinary radioactivity confirms B₁₂ malabsorption, but it does not identify the specific gastrointestinal defect. The second part of the Schilling test is then undertaken. The patient is given another oral dose of radiolabeled B₁₂ in addition to oral IF. Patients with pernicious anemia will demonstrate enhanced absorption (increased urinary radioactivity) in this second part of the test. The Schilling test has been largely supplanted by serologic tests for autoantibodies, including anti-IF and antiparietal antibodies.

### Lead Poisoning (Plumbism)

#### Description

Lead toxicity affects RBCs, renal epithelium, and the nervous system. It generally presents insidiously, with nonspecific features such as abdominal pain and cognitive impairment. However, it may present abruptly with vomiting, seizures, and altered mental status. In addition, lead poisoning may present as a microcytic, hypochromic anemia. Exposure to lead occurs through environmental sources, such as lead-based household paint, contaminated soil, lead plumbing, and manufacturing facilities.

Lead exerts its hematologic effects in 2 ways: inhibition of heme synthesis in the maturing erythrocyte and decreased survival of mature erythrocytes. Lead has a strong affinity for certain amino acids, particularly the sulfhydryl group of cysteine, and certain organelles, particularly mitochondria. Since heme synthesis takes place within mitochondria, and 2 enzymes instrumental in this process, delta-aminolevulinic acid dehydratase (δ-ALA) and ferrochelatase, are rich in the sulfhydryl groups, this process is exquisitely sensitive to lead. Ferrochelatase catalyzes the insertion of iron into the protoporphyrin ring. Its inhibition leads to the accumulation of free (iron-free) erythrocyte protoporphyrin (FEP), much of which binds nonenzymatically to zinc to form zinc protoporphyrin (ZPP). Separate from its effects on heme synthesis, lead inhibits ATPase-driven sodium channels, leading to increased osmotic fragility and hemolysis. Lastly, lead inhibits the enzyme 5′-nucleotidase, leading to basophilic stippling.

</tr>
<tr>
<td>Impaired transport</td>
</tr>
</tbody>
</table>
Despite all these vulnerabilities, anemia does not develop until blood lead levels are above 50 μg/dL. A blood lead level >10 μg/dL is considered elevated. Iron deficiency enhances the effects of lead toxicity in 2 ways. The absence of iron enhances the blockage of the ferrochelatase step in heme synthesis, and in an effort to absorb more iron, the gastrointestinal absorption of lead increases.

**Diagnosis**

Basophilic stippling is noted in the peripheral blood smear and in maturing erythroblasts in the marrow. The Centers for Disease Control and Prevention has defined lead poisoning as a blood lead level >10 μg/dL. Elevations in FEP and ZPP do not occur until blood lead levels exceed 35 μg/dL; thus, these assays are not sufficiently sensitive to screen for lead poisoning.

The advantage of FEP measurement, however, is that it can be performed reliably on small finger- or heel-prick samples. Furthermore, this assay can easily identify patients grossly intoxicated with lead. Elevated FEP and ZPP are not specific for lead poisoning and may also be seen in iron deficiency.

**Sickle Cell Anemia and Other Hemoglobinopathies**

**Description**

A hemoglobinopathy is a structural defect in Hb, usually resulting from a germline single-nucleotide point mutation in 1 of the Hb genes. There are examples of postsynthetic modifications in normally formed Hb, such as carboxyhemoglobin from carbon monoxide poisoning. The common hemoglobinopathies are listed in Table 10–12. In the United States, HbS is the most common abnormal Hb, followed by HbC, and HbE. Worldwide, HbS remains most common, but is followed closely by HbE (which is very common in Southeast Asia), followed by Hbs C, D, and G. In all, several hundred structurally abnormal Hbs have been described.

Homozygous sickle cell anemia (genotype SS, sickle cell disease) is associated with abnormal polymerization of Hb in red cells, leading to a cell with an altered shape that is rapidly cleared from the circulation. Polymerization of HbS is enhanced in hypoxic conditions. While normal red cells have a life span of about 120 days, the red cells in SS have an average life span less than 30 days. Hb electrophoresis shows that the red cells contain mostly HbS, with small quantities of HbF and HbA2. The clinical course in HbSS patients is one of chronic hemolysis punctuated by a wide range of complicating events (often called crises). Chronic hemolysis leads to a chronic anemia with growth retardation, delayed puberty, impaired exercise tolerance, jaundice, and cholelithiasis (due to the formation of pigmented gallstones). The patients are usually in need of intermittent transfusions. Episodic complications include vaso-occlusive events (eg, stroke, avascular necrosis of bone, splenic autoinfarction), splenic sequestration crises, aplastic crises (due most often to marrow infection with parvovirus B19), bacterial sepsis, and hyperhemolytic crises. The risk of bacterial infection is related to an underlying functional asplenia that affects most sickle cell patients by late childhood. This confers a particular susceptibility to infection by encapsulated bacterial organisms such as *Haemophilus influenzae* and *Streptococcus pneumoniae*. The most common cause of death in sickle cell disease is infection, followed by stroke and other thromboembolic events.

In the United States, HbS is the most common abnormal Hb, followed by HbC, and HbE. Worldwide, HbS remains most common, but is followed closely by HbE (which is very common in Southeast Asia), followed by Hbs C, D, and G.
Heterozygotes (genotype SA, sickle cell trait) are essentially asymptomatic and have normal red cell indices. The presence of sickle Hb can be detected by Hb electrophoresis, where it is found to represent about 35% to 45% of total Hb. When exposed to hypoxic conditions such as high altitude, these patients are at risk for splenic infarcts. Interestingly, patients who are double heterozygotes for HbS and β-thalassemia are more severely affected than heterozygous SA, having red cells that contain >50% HbS. Conversely, double heterozygotes for S-α-thalassemia manifest less HbS (<35%) and less severe symptoms.

HbE is relatively benign clinically, in both heterozygous and homozygous forms. Patients with HbE have red cell indices, however, that closely resemble those of a thalassemic patient (microcytic with high RBC count). HbE is prevalent in Southeast Asia. Double heterozygotes for S and E (SE disease) manifest moderate-to-severe hemolysis.

HbC disease (genotype CC) is generally associated with mild hemolysis, and heterozygotes (CA) are clinically normal. In both, target cells tend to be numerous in the peripheral smear. Patients who are doubly heterozygous for S and C (SC disease) have manifestations intermediate between SS and SA. While manifestations are generally milder than SS, there is a greater incidence of avascular necrosis of bone and retinal damage in SC than in SS. The peripheral blood film shows both sickle cells and target cells.

Hbs D and G are benign Hb variants. They can lead to confusion in interpreting an abnormal Hb electrophoresis, since they appear in the same location as HbS. However, these patients are clinically well.

**Diagnosis**

The identification of variant Hbs is usually performed with Hb electrophoresis. However, many laboratories now use high-performance liquid chromatography (HPLC). One limitation of both of these techniques is that several different variants can give similar results, although this is significantly less problematic in HPLC. Findings must be correlated with knowledge of the patient's clinical status and red cell indices before a definitive diagnosis can be rendered.

There are a number of screening tests for sickle Hb. These are based on the tendency of HbS to polymerize. A positive sickle screen is not specific for sickle cell disease, however, and can be present in sickle cell trait, SC disease, and Hb Charlem. Furthermore, a negative screening test does not entirely exclude HbS, particularly in infants who may still have significant quantities of HbF, which inhibits polymerization of HbS.

**Hereditary Spherocytosis**

**Description**

HS was once known as hereditary hemolytic jaundice. Its cardinal features are chronic hemolysis, jaundice, and splenomegaly. It is a fairly common condition, particularly among people of Northern European descent, in whom it is the most common inherited red cell disorder. In the United States the incidence is about 1 in 5000. HS is usually transmitted as an autosomal dominant trait, but about 25% of affected families display autosomal recessive inheritance. This variation derives from the fact that HS can be caused by any 1 of several defects in RBC cytoskeletal proteins, including band 3, protein 4.2, spectrin, and ankyrin. A deficiency in any of these components leads to cytoskeletal instability. Subsequently, there is loss of the biconcave shape in favor of the stoichiometrically more attainable sphere.

The plurality of underlying molecular defects also contributes to clinical heterogeneity, with phenotypes ranging from mild to severe. HS may present early as neonatal jaundice, or it may present in late childhood with splenomegaly and mild anemia. While anemia in some cases is quite severe, in most cases the hemolytic anemia is mild and well compensated by the marrow. Some patients require splenectomy, which usually results in clinical remission. However, splenectomy carries with it an increased susceptibility to bacterial sepsis. As HS patients age, they are at risk for pigmented gallstones.

**Diagnosis**

The peripheral blood film shows numerous spherocytes. These appear as red cells that lack central pallor. Larger polychromatophilic cells are often numerous, reflective of an increased reticulocyte
count. While spherocytes are typically smaller than normal red cells, the MCV may be low, normal, or high, owing to reticulocytosis. The MCHC is characteristically increased.

When numerous spherocytes are observed on a peripheral blood film, the 2 primary considerations are immune hemolysis and HS. Immune hemolysis can usually be excluded with a negative direct antiglobulin test (DAT, Coombs test).

The osmotic fragility test can be useful in supporting the diagnosis of HS. However, spherocytes from any cause will result in a positive test.

**Hereditary Elliptocytosis (HE)**

**Description**

This autosomal dominant disorder is due to defective tetramerization of cytoskeletal spectrin, resulting in elliptocytes, also called ovalocytes. There are several clinical variants. The common type of HE is seen primarily in African Americans and manifests as a mild lifelong hemolytic anemia. Hereditary pyropoikilocytosis is a variant of HE in which RBCs are exquisitely sensitive to damage from heat. The peripheral blood smear is notable for a profound degree of poikilocytosis with red cells of every size and shape. This condition is usually most pronounced in infancy and tends to abate with age, giving way to a phenotype of common HE. A stomatocytic type of HE exists that is also called Southeast Asian ovalocytosis. This phenotype confers some protection against infection by *P. vivax* malaria.

**Diagnosis**

There is no specific laboratory test for HE. The diagnosis depends on finding elliptocytes in the peripheral blood. By definition, these cells are twice as long as they are wide, and in HE they comprise more than 25% of all red cells. Elliptocytes are not unique to HE and may be seen in iron deficiency anemia and thalassemia. The proportion of elliptocytes is usually much less than 25% in these other conditions, and they are easily excluded on other grounds. Once these are ruled out, the diagnosis is made of HE.

**Autoimmune Hemolytic Anemia**

**Description**

When an antibody attaches to a red cell, the consequences depend largely on the nature of the antibody. Some antibodies are capable of activating complement and producing brisk intravascular hemolysis. Others behave as opsonins, promoting red cell destruction in the spleen. Some antibodies react only in a cold environment, some only in warmth. Some coat the red cell and do nothing more.

These disorders present with the typical manifestations of anemia, with variable rates of onset. Mild splenomegaly is common when hemolysis is extravascular. Dark urine, abdominal or back pain, and fever may accompany intravascular hemolysis. In severe IgM-induced cold autoimmune hemolytic anemia (CAIHA), the skin may have a livedo reticularis pattern, and there may be acrocyanosis on exposure to cold.

Warm autoimmune hemolytic anemia (WAIHA) is mediated by IgG autoantibodies that optimally bind RBCs at body temperature (37°C). The red cell antigens most commonly the target in WAIHA are the Rh antigens. IgG molecules must form cross-links to activate complement, and the target red cell antigens in WAIHA are usually insufficiently dense on the red cell surface to permit this. A higher-density antigen is involved in a condition known as PCH, described below. Thus, IgG antibodies opsonize the red cell in WAIHA, leading to membrane damage mediated by splenic macrophages with the formation of small, spherocytic, cells (microspherocytes). In some cases, there is concomitant immune thrombocytopenia, and this association is known as Evans syndrome.

CAIHA, also called cold agglutinin disease, is mediated by IgM antibodies that bind RBCs at lower temperature ranges. The target antigens are usually the red cell antigens I or i. Those binding over a limited thermal amplitude (eg, 0°C-22°C) will obviously not produce clinical consequences. However, these antibodies may cause difficulty in the laboratory, where studies are routinely carried out at room temperature, which could be within this thermal amplitude.
Antibodies with broader thermal amplitude may bind to red cells in the extremities, where temperature falls a bit below core body temperature, resulting in acrocyanosis. IgM antibodies are capable of activating complement. Most often, the clinical consequence is a result of opsonization by C3, leading to extravascular hemolysis similar to that seen in WAIHA. C3-mediated hemolysis is more of a hepatic process than a splenic one. Sometimes, however, the complete complement cascade is activated on the cell surface, resulting in intravascular hemolysis.

Both WAIHA and CAIHA are often idiopathic conditions. However, a significant number are secondary to another underlying condition, including lymphoid neoplasms (eg, chronic lymphocytic leukemia), medication use, systemic autoimmune diseases (eg, systemic lupus erythematosus), immunodeficiency (eg, common variable immunodeficiency), and infection (infectious mononucleosis, HIV, and Mycoplasma pneumoniae).

Paroxysmal cold hemoglobinuria (PCH) is caused by IgG antibodies that are directed at the red cell P antigen. The antibody responsible for PCH is called the Donath–Landsteiner antibody. This particular IgG antibody has peculiar tendencies, including the binding of red cells in colder temperatures (in the blood of the extremities) and the activation of complement, producing intravascular hemolysis. Originally described in association with syphilis, the antibody now is more often seen in children with viral infections. Mortality can be quite high, up to 30%.

Drug-induced immune hemolytic anemia arises through several pathophysiologic mechanisms (Table 10–13). An antibody may be raised against a drug that is capable of adhering nonspecifically to the red cell membrane (drug adsorption or hapten mechanism). Second, drug–antibody immune complexes may coat the red cell surface (immune complex mechanism). What distinguishes these first 2 mechanisms is that the antibody is directed against the drug, not a red cell antigen. Lastly, a drug may be responsible for eliciting a true autoimmune hemolytic anemia, with antibody against red cell antigens. This condition is clinicopathologically indistinguishable from AIHA, and it may or may not abate when the drug is discontinued.

Lastly, alloimmune hemolytic anemia is due to transfusion of red cells bearing an antigen foreign to the recipient. Most responsible antibodies arise as a result of prior sensitization, commonly prior transfusion or pregnancy, and most cause extravascular hemolysis of mild-to-moderate severity. In the case of ABO antigens, the antibodies are naturally occurring, and prior sensitization is not required for there to be a problem. Furthermore, ABO antibodies produce severe intravascular hemolysis, which can be fatal.

**Diagnosis**

The DAT, also known as the direct Coombs test, is pivotal for the diagnosis of immune hemolysis. This test is capable of demonstrating the presence of antibodies or complement on the surface of RBCs.

Additional laboratory findings include anemia, reticulocytosis, indirect hyperbilirubinemia, decreased haptoglobin, and an increased LDH. The peripheral blood smear often demonstrates spherocytes, polychromasia, and, in severe cases, nucleated red cells. In cold agglutinin disease, red cell clumping is seen.

An important consequence of red cell antibodies is their tendency to interfere with pretransfusion testing.

Hemolytic Disease of the Newborn (HDN)

Description
If there is mingling of fetal and maternal blood (a fetomaternal hemorrhage), then the mother can become sensitized to antigens of the fetal blood cells. Some of these antigens are paternal in origin and may therefore be foreign to the mother, and a maternal antibody reaction may occur. If the antibody idiotype produced is one that can cross the placenta (most IgG subtypes can cross the placenta, IgM cannot), it can produce fetal hemolysis.

The severity of fetal hemolysis depends on several factors, including the identity of the immunizing antigen and the titer of maternal antibody. The pregnancy that creates sensitization is usually spared, as the initial reaction produces largely IgM that does not cross the placenta. In subsequent pregnancies, an IgG-mediated anamnestic response may be raised, producing HDN. Furthermore, pregnancy-induced maternal sensitization may complicate future transfusions.

When this syndrome was first recognized, it was most commonly associated with antibodies to the Rh antigen known as D. This D antigen is the basis for categorizing blood types as Rh+ or Rh−. However, prevention strategies have reduced the incidence of RhD HDN to about 0.1% of all pregnancies. The incidence of maternal anti-Kell antibody now exceeds that of anti-D antibodies in many centers.

If a pregnant woman does have antibodies against a fetal antigen, the fetus is at risk for HDN. Mild HDN may only manifest as compensated hemolysis in which fetal erythropoiesis is capable of keeping up with the rate of red cell destruction. Severe HDN manifests with fetal anemia, hyperbilirubinemia, and numerous circulating nucleated RBCs (erythroblastosis fetalis). Hypoproteinemia may ensue, leading to decreased serum osmotic pressure, and severe edema (hydrops fetalis). A pregnancy in which there is known sensitization (maternal antibodies to fetal red cell antigens have been detected) must be monitored to determine the severity of fetal hemolysis.

RhD HDN is prevented by the administration of Rh immune globulin (RhIg) to Rh-negative women during pregnancy. RhIg binds to and effectively conceals D antigenic sites, precluding an immune response. RhIg is given routinely at 28 weeks, at term, and whenever a fetomaternal hemorrhage is suspected (amniocentesis, trauma, abortion, abruption, etc).

Diagnosis
Several laboratory tests support the diagnosis and treatment of HDN. First, there is blood typing to confirm the maternal, paternal, and neonatal Rh status.

Second, in Rh-negative women, a screening test for antibodies must be performed. This is a test in which maternal serum is incubated with a panel of red cells having known antigenic status. If an alloantibody is detected, its titer is determined by serially diluting the sample until reactivity is abolished. If a titer of >1:32 is present, the risk of HDN is considered sufficiently high to warrant fetal monitoring.

In Rh-negative women with alloantibodies, the fetus must be monitored to determine the severity of hemolysis. Amniocentesis is performed to determine the quantity of amniotic fluid bilirubin. When low, monitoring is continued. When high, consideration is given to therapeutic intervention, including intrauterine transfusion and, when possible, delivery.

In Rh-negative women without antibodies, laboratory tests are available to confirm and quantify a fetomaternal hemorrhage. These include the Kleihauer–Betke test, the erythrocyte rosette test, and others. If positive, a dose of RhIg may be given.

Microangiopathic Hemolytic Anemias

Description
This group of disorders shares the ability to create a microvascular environment capable of shredding red cells. They do this usually by inducing endothelial injury and thrombosis, generating a jagged lattice of fibrin against which red cells are thrust with the pressure of arterial blood. The result is intravascular hemolysis and the appearance of schistocytes in the peripheral blood film. Often the creation of thrombi is so brisk that thrombocytopenia results. The disorders associated
with MHA include disseminated intravascular coagulation (DIC), thrombotic thrombocytopenic purpura (TTP), hemolytic uremic syndrome (HUS), and the pregnancy-associated syndrome of hemolysis, elevated liver enzymes, and low platelets (HELLP). A similar clinical picture can be created by malignant hypertension and macrovascular red cell trauma caused by mechanical heart valves.

**Diagnosis**
The peripheral blood smear shows schistocytes and, usually, thrombocytopenia. The associated conditions are clinicopathologic diagnoses for which there is no single diagnostic test.

**Glucose-6-phosphate Dehydrogenase (G6PD) Deficiency**

**Description**
This is the most common red cell enzyme defect. Since red cells lack a nucleus, they lack the capacity to make new enzymes. Even normal red cells have greater enzymatic capacity when young than when old. However, if the activity of a critical enzyme significantly degrades before the average red cell life span (120 days), then the cell dies prematurely. Red cells rely on G6PD to produce glutathione that absorbs oxidant stress to protect Hb from oxidation. Oxidized Hb forms precipitates within the red cell, known as Heinz bodies, whose excision by splenic macrophages results in bite cells.

There are numerous defective forms (disease-causing alleles) of G6PD. Most abnormal alleles result in a functionally normal enzyme but have a shortened life span within the red cell. Uncommon alleles result in decreased G6PD production, and even young cells have low activity in these cases. In most forms of the disease, young red cells, especially reticulocytes, have normal G6PD activity, whereas, in other forms, enzyme activity is universally decreased. Furthermore, the magnitude of this decrease varies. This heterogeneity results in 3 classes of G6PD deficiency: class 1, in which there is chronic low-level hemolysis; class 2, in which there is profound intravascular hemolysis following oxidant stress; and class 3, in which there is mild-to-moderate intravascular hemolysis following oxidant stress.

Most G6PD-deficient persons are clinically well until exposed to excess oxidant (class 2 or 3). Such exposures arise in the form of ingestion (eg, fava beans), medication use (eg, nitrofurantoin, antimalarials, sulfa drugs), or infection. In most individuals, there is preferential destruction of older red cells.

**Diagnosis**
The peripheral smear shows a combination of bite cells and Heinz bodies. The latter require special (supravital) staining in order to be visualized. Laboratory assays are available for measuring G6PD activity. G6PD activity may appear normal during an acute episode, because only nonhemolyzed, younger cells are available to be assayed. If a normal result is obtained, consider repeating the assay in 3 months.

**Pyruvate Kinase (PK) Deficiency**

**Description**
A steady generation of ATP is needed to maintain the integrity of the red cell membrane. Red cells generate ATP principally via the glycolytic pathway, in which PK is an active enzyme. Deficient ATP production leads to progressive red cell dessication, causing predominantly extravascular hemolysis.

PK deficiency is usually a recessively inherited condition. The disease is worldwide in distribution but slightly more concentrated in particular populations, notably people of Northern Europe descent and the Pennsylvania Amish.

**Diagnosis**
Echinocytes are the classic peripheral smear finding, but these appear in large numbers only after splenectomy. An autohemolysis test is positive and corrects with the addition of ATP. A fluorescent spot test is performed in which red cells are incubated with NADH (which fluoresces) to check for conversion to NAD (which does not).
**Paroxysmal Nocturnal Hemoglobinuria**

**Description**
Complement activation occurs at a low level continuously in the blood, and formed C3b that does not bind to an available surface (bacterium, leukocyte, platelet, or RBC) is rapidly degraded. Bound C3b can proceed to induce lysis of the cell to which it is attached. Thus, blood cells must have a mechanism for regularly shedding C3b to avoid lysis.

PNH is due to an acquired (somatic) mutation in the *PIG-A* gene of a hematopoietic stem cell, the major consequence of which is decreased production of the glycosylphosphatidylinositol (GPI) anchor. This is a molecule that functions as a transmembrane anchor for several surface proteins, many of which are involved in protecting the cell from complement lysis. Affected cells have decreased expression of, among others, CD16 (the F(c) receptor type III), CD55 (decay-accelerating factor [DAF]), and CD59 (membrane inhibitor of reactive lysis [MIRL]). Since this defect is found within an early stem cell, all cell lines (red cells, white cells, platelets) are affected.

PNH manifests as hemolysis, and its severity oscillates. Hemoglobinuria reflects the intravascular nature of the hemolysis. While hemolysis tends to be episodic (paroxysmal), some patients experience chronic hemolysis of uniform intensity. Furthermore, exacerbations are not usually nocturnal as implied in the original description. PNH is associated with a thrombotic tendency that can be the initial manifestation. Over time the disease may evolve to or present as aplastic anemia.

**Diagnosis**
A sucrose hemolysis test or acidified serum (Ham) test may be used to screen for PNH. In these assays, patient blood is exposed to an environment that promotes complement activation. Enhanced hemolysis in the patient sample as compared with a normal control is interpreted as a positive test. The preferred diagnostic modality is flow cytometry, a test that allows quantitation of the surface proteins known to be diminished in PNH.

**Sideroblastic Anemia**

**Description**
In the developing erythrocyte, it is within mitochondria that iron is incorporated into porphyrin to make heme. Ringed sideroblasts are the morphologic expression of the abnormal sequestration of iron within mitochondria. When increased ringed sideroblasts are found, the differential diagnosis includes myelodysplastic syndrome, alcohol abuse, copper deficiency (Wilson disease), lead toxicity, medication effect (isoniazid, pyrazinamide), pyridoxine (vitamin B6) deficiency, and hereditary sideroblastic anemia.

**Diagnosis**
In the peripheral blood, one finds anemia with a dimorphic red cell population; that is, there are normocytic macrocytes and hypochromic microcytes. The diagnosis of sideroblastic anemia requires a bone marrow biopsy. Nonringed sideroblasts, defined as red cell precursors with 1 to 4 faint siderotic granules, are normal in the marrow. Ringed sideroblasts are defined as red cell precursors with at least 10 siderotic granules that surround at least one third of the nucleus. Although they may be seen in small number in some normal individuals and in a wide range of disorders, when they are found in >15% of all red cell precursors, the diagnosis of sideroblastic anemia is made.

**Pure Red Cell Aplasia**

**Description**
Aplastic anemia is a term that refers to the complete absence of hematopoiesis, affecting granulocytic precursors, erythroid precursors, and megakaryocytes. A proliferative disorder may be isolated to a single cell line, however, as is the case in pure red cell aplasia. This condition may be acquired or congenital. Acquired pure red cell aplasia may be due to thymoma, EPO therapy, or infection with parvovirus B19.
Parvovirus B19 may cause a transient arrest of red cell production in healthy children and adults without serious consequences. Infection usually lasts about 2 weeks, and in those with a normal red cell life span of 120 days, this usually goes unnoticed. However, in those with chronic hemolytic anemia, a transient arrest of erythropoiesis may be catastrophic. The virus infects erythroid progenitor cells, causing a maturation arrest at the pronormoblast stage. Marrow examination finds numerous giant pronormoblasts, a reduction of the more mature forms, and viral nuclear inclusions.

Congenital pure red cell aplasia (Blackfan–Diamond syndrome) is a rare, constitutional red cell aplasia, which usually becomes evident by the age of 5 years. Erythroid precursors in the marrow are typically low or absent. HbF is increased.

**Diagnosis**
The diagnosis is made in a patient with isolated anemia, which is usually normocytic, with reticulocytopenia. The bone marrow biopsy shows an isolated decrement in erythropoiesis.

---

**ERYTHROCYTOSIS**

**Definition**
Erythrocytosis was traditionally defined as persistent elevation in the RBC mass. Since RBC mass is not easily measured, the current WHO definition relies on Hb, specifically Hb above 18.5 g/dL in men and 16.5 g/dL in women.

**Differential Diagnosis**
The primary considerations are myeloproliferative neoplasms (MPNs; polycythemia vera [PV]), reactive (secondary) erythrocytosis, and spurious erythrocytosis due to dehydration (Gaisbock syndrome) (Table 10–14). Secondary polycythemia is associated with low PaO₂ states (such as smoking and living at high altitudes), abnormal Hb variants, and certain neoplasms (renal cell carcinoma, cerebellar hemangioblastoma) that produce elevated EPO.

**Polycythemia Vera**

**Definition**
PV is an MPN that is due to a clonal neoplastic proliferation of erythroid precursors. It presents at a mean age of 60, most commonly with hypertension, thrombosis, pruritus, erythromelalgia, or headache. The erythrocytosis is usually normocytic. Neutrophilia and basophilia are common, and sometimes thrombocytosis is present. The cause of death is most commonly thrombosis. Some patients, however, progress to acute leukemia.

LAP, leukocyte alkaline phosphatase; EPO, erythropoietin.
Diagnosis

The diagnosis of PV is made according to strict criteria (Table 10–15). The RBC mass is measured using isotope dilution, in which a sample of patient red cells is labeled with a radioactive isotope and reinfused. The red cell mass can then be calculated from the degree of dilution of the labeled red cells. This direct measurement of the red cell mass distinguishes reduced plasma volume from a true absolute erythrocytosis.

Examination of the bone marrow shows a marked expansion of erythroid precursors. In PV, erythroid precursors are capable of spontaneous erythroid colony formation in vitro. In testing for endogenous erythroid colony formation, patient marrow is cultured. In PV, one can observe the spontaneous formation of erythroid colonies (without addition of EPO). In healthy patients or those with secondary erythrocytosis, erythroid colony formation requires exogenous EPO.

The janus kinase 2 (JAK-2) mutation has now been identified in >80% of PV cases. The JAK-2 mutation is a valine to phenylalanine substitution at codon 617 (Val617Phe) that appears to confer cytokine-independent growth to cells bearing it.

METHODS

Red Cell Indices

Measurement of total Hb is carried out most commonly through a chemical reaction. In the cyanohemoglobin (hemoglobin cyanide [HiCN]) method, Hb is converted to HiCN whose concentration is measured by spectrophotometry. The absorbance of the solution at 540 nm reflects the amount of Hb originally present.

The Hct can be measured directly (manual technique), by centrifuging a tube of whole blood. The ratio of the packed red cell column height to the total height is the Hct. Note that the Hct is a unitless value (a percentage), as the units cancel out in its calculation.

Erythrocytes (as well as leukocytes and platelets) can be counted manually, through the use of a hemocytometer. This is a labor-intensive method that is still used when, for various reasons, the automated analyzer gives erroneous results. RBC counts may be given in terms of cells per mm³ (eg, 5.5 × 10⁹/mm³), per μL (conventional units), or per L (SI units). When the Hct and RBC count are determined manually, the remaining red cell indices can be calculated. For example, MCV = Hct × 1000/RBC. The MCV is stated in femtoliters.

Automated techniques are widely used in clinical laboratories. On most instruments, the red cell count (RBC), MCV, and RDW are measured directly (as is the total Hb). The instrument then calculates the other indices, such as Hct. There are at least 3 different methods used by automated instruments to count cells: impedance (counts any particle of given size), optical methods (light scatter), or combination of impedance and light scatter.

In impedance counting, cells are suspended in a conductive diluent and passed one-by-one through an aperture across which a current is flowing. A cell within the aperture causes a
momentary increase in electrical resistance (impedance). Voltage, a product of resistance and current \( (V = I \times R) \), increases when the resistance increases. The instrument interprets a momentary increase in voltage as a single cell. The amount of voltage change is proportional to the size of the cell. The instrument is programmed to count particles measuring between 36 and 360 fl as red cells. Of course, leukocytes, which are within this size range, will be counted as erythrocytes, but their relative number is so small (usually) that their effect is typically negligible. RBCs passing through the aperture come in a range of sizes (volumes), distributed in a roughly Gaussian curve. The mean of this distribution is taken as the MCV. The variance in the curve is the RDW. The rest of the red cell indices can be calculated as follows: \( \text{Hct} = \text{MCV} \times \text{RBC} \); \( \text{MCHC} = \frac{\text{Hb}}{\text{Hct}} \times 100 \).

**Reticulocyte Counting**

Reticulocytes can be measured manually or by automation. In the manual method, a blood smear is stained with a supravital dye (eg, new methylene blue) that highlights the endoplasmic reticulum that persists within reticulocytes. Red cells and reticulocytes are counted, and the result is given as a percentage (number of reticulocytes per 100 red cells).

Automated methods are more accurate, since many more cells can be counted. A blood sample is incubated with a supravital dye, and then passed through an automated counter in which they are exposed to a laser. Light scatter (which will be greatest in stained reticulocytes) is used to enumerate the reticulocytes.

Normally reticulocytes constitute less than 1.5% of all red cells. This proportion increases when red cells are lost or destroyed peripherally, reflecting a marrow response. A normal reticulocyte count in the face of anemia is indicative of an impaired marrow.

However, the reticulocyte percentage can be somewhat misleading in the presence of anemia. This is because anemia leads to increased EPO production, and EPO stimulates the proliferation of red cell precursors and stimulates the release of reticulocytes from the marrow. Even if the marrow capacity for proliferation is impaired, the latter effect can produce a transient appearance of reticulocytosis. Thus, to correct for this, one can calculate the reticulocyte index (RI): \( \text{RI} = \text{reticulocyte percentage} \times \left( \frac{\text{patient's HCT}}{\text{normal HCT}} \right) \). A normal RI is <3%.

**Hemoglobin Electrophoresis**

Electrophoresis is the separation of proteins through the application of voltage. Most proteins have a net charge, usually a net negative charge, and when placed into a semisolid medium (a gel) will move in response to a voltage. The distance that a protein moves depends on its size and the magnitude of its charge, so that different proteins can be separated from one another. The positively charged electrode attracts negatively charged proteins and is called the anode. Proteins that end up closest to the anode are called fast-migrating or anodal. Proteins that end up farthest from the anode are considered slow-migrating or cathodal.

If RBCs are lysed, the predominant protein within the lysate is Hb. In the normal adult, this Hb is largely HbA, with about 2% to 3% HbA2. When this lysate is applied to a gel across which a voltage is applied, the result is a prominent band (HbA) near the anode (fast-migrating) and a dim band (HbA2) near the cathode. Any deviation from this pattern is indicative of a hemoglobinopathy or thalassemia. Routine Hb electrophoresis is performed by placing a sample of lysed blood on a cellulose acetate gel at pH 8.6 (alkaline electrophoresis). The gel is subjected to electromotive force, fixed, and stained.

Thalassemia, being a quantitative defect in production of entirely normal Hbs, does not produce abnormal bands on the electrophoresis. Instead, \( \beta \)-thalassemia is diagnosed by the presence of “thalassemic indices” (low Hct, increased RBC count, low MCV) and a quantitatively increased HbA2. \( \alpha \)-Thalassemia has “thalassemic indices” and normal HbA2.

True hemoglobinopathies are due to production of a structurally abnormal Hb molecule that usually produces a distinct band on electrophoresis. The identity of most, but not all, abnormal Hbs can be determined by routine electrophoresis, particularly when supplemented with some clinical information and CBC data. When there is uncertainty, electrophoresis on citrate agar at pH 6.2 (acid electrophoresis) produces a different set of electrophoretic positions that, in combination with the alkaline gel, can help identify an abnormal band.
Screening Tests for Sickle Hemoglobin

Rapid detection of sickling Hb, without having to perform electrophoresis, is possible with 1 of 2 types of assay. In the first, the Hb solubility (dithionate) test, one can detect insoluble forms of Hb within a lysate of blood. Red cells are lysed in sodium dithionate buffer with saponin. After several minutes, marked turbidity indicates a positive screen. Note that this test detects free Hb with altered solubility and may be positive in a number of different genotypes: SS, SA, SC, SD, and some types of HbC. This test may be negative when the concentration of HbS is too small, for example, in neonates.

The second type of screening test, the sickling (metabisulfite) test, detects red cells with sickling Hbs. In this test, whole blood is subjected to metabisulfite, which encourages cells containing HbS to sickle. A smear is then examined microscopically for sickling. Like the solubility test, this test does not give genotypic information and may be positive in SS, SA, SC, S-other, and some types of HbC. The test requires at least 10% HbS to be positive. Thus, it may not be positive in neonates or those very aggressively transfused.

Osmotic Fragility Test

All red cells expand and eventually undergo lysis in a hypotonic environment, and spherocytic red cells do so at a faster rate than normal biconcave red cells. This is the basis of the osmotic fragility test. Red cells are incubated in progressively more hypotonic solutions, parallel with normal controls. Enhanced lysis, as compared with controls, is a positive test. A positive osmotic fragility test is not diagnostic of HS, however, since red cells that are spherocytic from any cause will give a positive result. The most common acquired cause of red cell spherocytosis is autoimmune hemolytic anemia.

Direct Antiglobulin Test (Coombs Test)

The reagent used in this test is an antibody, obtained from rabbit or goat, that reacts with (binds to) human globulins (anhuman globulin [AHG]). Specifically, these antibodies may have reactivity with IgG, complement protein C3, or both. Patient blood is mixed with AHG and then observed for agglutination (clumping). Depending on the reagent used, agglutination suggests that the patient's red cells are coated with IgG, C3, or both. Furthermore, since these were not added to the red cells in vitro, agglutination indicates that coating occurred in vivo.

In the usual case of WAIHA, the red cells agglutinate mainly with anti-IgG. There may or may not be reactivity with anti-C3. In cold agglutinin disease, red cells agglutinate only with anti-C3. While the titer of a warm autoantibody provides little useful clinical information, the titer of a cold agglutinin can be helpful. The cold agglutinin titer is the highest dilution of patient serum that causes agglutination of normal RBCs.

Kleihauer–Betke Test

The Kleihauer–Betke (acid elution) test is based on the observation that a weak acid is capable of eluting normal HbA out of red cells. In contrast, HbF is resistant to acid elution and remains within red cells. Thus, if blood is subjected to a weak acid, and then smeared and stained, the cells containing HbA will appear as pale “ghosts,” whereas cells containing HbF appear bright red. In a pregnant woman, the presence of red cells with HbF is indicative of a fetomaternal hemorrhage.

REFERENCES

The coagulopathies are grouped into disorders of bleeding and thrombosis. The hemorrhagic diseases are further subdivided into the 2 major categories of coagulation factor disorders and platelet disorders. To understand the diseases with abnormal coagulation that follow, a brief introduction to normal hemostasis precedes the discussions of the diseases.
Normal hemostasis is the controlled activation of coagulation factors and platelets leading to clot formation, with subsequent clot lysis, in a process that stops hemorrhage without excess clotting (thrombosis). Effective hemostasis is a rapid and localized response to an interruption in vascular integrity (vessel wall injury), such that clots are formed only when and where they are needed.

**Clot Formation**

Clot formation involves platelet activation and the subsequent generation of fibrin via the coagulation cascade. The 2 processes are discussed separately in the sections that follow.

**Platelet Plug Formation**

Platelet plug formation is initiated in vivo by exposure of platelets to vascular subendothelium when a vessel is injured. The platelets adhere to the subendothelium, spread out along the surface, and release substances that promote the aggregation of other platelets at that site. The platelets also accelerate fibrin clot formation by providing a reactive surface for several steps in the coagulation cascade.

Adhesion of platelets to the subendothelial surface is facilitated by a plasma protein, von Willebrand factor (vWF), especially in vessels with high shear forces (eg, the fast blood flow in arteries has a higher shear force than slow blood flow in veins). vWF binds to a specific receptor on the platelet surface. Deficiency of vWF results in poor adherence of platelets to subendothelium. The severity of bleeding in von Willebrand disease (vWD) varies widely among patients. Another related platelet adhesion defect occurs in patients whose platelets lack the receptor for vWF. This bleeding disorder, known as Bernard–Soulier disease, results from an inability of platelets to bind vWF.

Platelet activation occurs from interaction of platelet agonists, most of which are soluble, with specific receptors on the platelet membrane. Physiologically important agonists include adenosine diphosphate (ADP), thrombin, epinephrine, collagen, and thromboxane A2, which is derived from arachidonic acid. A sequence of membrane and cytoplasmic events is initiated by the agonist–receptor interaction, involving an increase in cytoplasmic calcium ion concentration and a platelet shape change from a disc to a spiny sphere. The change in cytoplasmic calcium concentration leads to contractile events in the platelet, causing alpha and delta granules (also known as dense bodies) to fuse with the platelet plasma membrane and release their granule contents into the extracellular space. Successful granule release requires the formation of thromboxane A2 from endogenous arachidonate via the enzyme cyclooxygenase. This enzyme is inhibited irreversibly by aspirin and inhibited reversibly by a number of other anti-inflammatory agents. Treatment with aspirin can cause a platelet secretion defect (reduced release of granule contents) that is often clinically significant in patients with underlying coagulopathies. Alpha granules contain vWF, fibrinogen, Factor V, 2 platelet-specific proteins—platelet factor 4 (PF4) and beta-thromboglobulin—as well as a number of other proteins. Delta granules contain serotonin, adenosine triphosphate (ATP), ADP, pyrophosphate, polyphosphate, and calcium. The release of some of these substances, in particular ADP, activates unstimulated platelets nearby. Absence or deficiency of alpha or delta granules occurs as a feature of several congenital and acquired platelet function disorders, collectively known as storage pool disorders. Individuals whose platelets possess appropriate numbers of intact granules that cannot be released on appropriate stimulation have a platelet release defect, and on that basis also may have a bleeding tendency. Aspirin is a common cause of a platelet release defect, because it impairs thromboxane production.

Release of platelet granule contents is followed by platelet aggregation, that is, the binding of platelets to one another to form the platelet plug. Normal aggregation requires fibrinogen binding to platelets via the fibrinogen receptor, which is the glycoprotein IIb/IIIa complex (GP IIb/IIIa), on the platelet surface. Congenital absence of GP IIb/IIIa results in a bleeding diathesis known as Glanzmann thrombasthenia (GT).
The platelet surface serves as a site for certain coagulation pathway enzyme reactions (see below). For example, the platelet membrane can bind the Factor Xa/Factor Va complex that activates prothrombin to thrombin. Thus, platelet activation and fibrin formation via the coagulation cascade are interactive biological processes.

**Fibrin Clot Formation**

The coagulation factor pathway is an enzymatic cascade with sequential conversion of proenzymes (zymogens) to fully activated enzymes, which then convert other zymogens to their activated forms (Figure 11–1). The final steps directly preceding fibrin formation can be activated through both the intrinsic and extrinsic pathways; hence, this part of the pathway is called the common pathway. Numerous positive and negative feedback mechanisms exist in the coagulation pathways so that the cascades do not proceed in an uncontrolled fashion. The pathways are now known to be extremely complex, with multiple interactions between factors in the intrinsic, extrinsic, and common pathways. The following description is a version of coagulation factor interactions that highlights the fundamental reactions.

The coagulation cascade is activated by the appearance of tissue factor (also historically known as Factor III), which is not normally exposed. Tissue factor is presented when a blood vessel is injured. It binds with Factor VII and small amounts of circulating active Factor VII (Factor VIIa), resulting in a complex of Factor VII or VIIa and tissue factor. The Factor VII in the complex can be autoconverted to Factor VIIa, resulting in a greater number of Factor VIIa–tissue factor complexes. This complex activates Factor IX to Factor IXa in the intrinsic...
In addition, thrombin activates Factor XI to Factor Xla, which, like Factor VIIa and tissue factor, activates Factor IX to Factor IXa. Thrombin catalyzes the conversion of fibrinogen to fibrin, which is then cross-linked by Factor XIII to create a stabilized form of fibrin (clot). Factor XIII is also activated to Factor XIIIa by thrombin.

Factor XII, prekallikrein (PK), and high-molecular-weight kininogen (HMWK, shown as HK in Figure 11–1) are not required for the generation of fibrin in vivo because even when they are completely absent, there is no increased risk for bleeding. Nevertheless, the intrinsic pathway is activated when Factor XII contacts collagen (exposed by vessel injury) or polyphosphate (released from activated platelets).

This cascade, as it is currently understood and described above, explains 2 long-standing clinical observations. First, it explains the significant bleeding tendency associated with Factors VIII and IX deficiencies because these factors are important in the early stages of cascade amplification. Factor VIIa and tissue factor activate Factor IX to Factor IXa, and Factor IXa requires Factor VIII to convert Factor X to Factor Xa. Second, this scheme provides an explanation for the clinical observation that deficiencies of Factor XII, PK, and HMWK are not associated with an increased risk for bleeding because Factor VIIa/TF activates Factor IX, and thrombin activates Factor XI, bypassing the need for Factor XII.

Two of the coagulation cascade reactions occur on the platelet surface. The first of these is the activation of Factor X to Factor Xa, which is produced by platelet-bound Factor IXa and platelet-bound Factor VIIIa. In the second, platelet-bound Factor Xa and platelet-bound Factor Va convert prothrombin (Factor II) to thrombin (Factor IIa) in a subsequent step in the coagulation sequence. As noted below, single factor deficiency states, most of which are congenital, exist for all of the factors, but multiple factor deficiencies, which are usually not congenital, are much more commonly encountered. Inhibitors, as antibodies directed against a specific coagulation factor, can arise to any of the individual factors to create deficiency states. With some exceptions, most factor inhibitors are rare.

There are 2 major inhibitory pathways that determine the rate at which the cascade is amplified. One of these is the protein C–protein S anticoagulant pathway. An additional mechanism for control of the coagulation cascade involves the inhibitory action of antithrombin.

An additional mechanism for control of the coagulation cascade involves the inhibitory action of antithrombin (formerly known as antithrombin III) (Figure 11–3). Antithrombin has a limited anticoagulant effect on its own, but in the presence of heparin or selected other negatively charged heparin-like molecules, antithrombin adopts a new conformation that increases its inhibitory activity 1000-fold, permitting it to inhibit most of the activated coagulation factors in complexes where both antithrombin and heparin bind to the activated coagulation factor. Inhibition of Factor Xa, however, does not require the direct binding of the activated coagulation factor by heparin. Factor Xa can be neutralized when it is bound only to antithrombin, after antithrombin has been activated by heparin or related molecule. The antithrombotic action of short chains of heparin (low-molecular-weight heparin) is directed primarily against Factor Xa.

because short heparin chains inhibit predominantly only Factor Xa (longer chains are required for Factor IIa inhibition). Fondaparinux, a synthetic heparin-related pentasaccharide, inhibits Factor Xa exclusively.

It should be noted that all of the coagulation factors in the coagulation cascade are synthesized in the liver, and that the activity of Factors II, VII, IX, and X is vitamin K-dependent. Tissue factor is constitutively expressed on some cell types, and in other cell types, such as endothelial cells, it is not normally expressed. There is little (if any) tissue factor in the circulating plasma under normal conditions. It is not exclusively synthesized in the liver. Tissue factor in the subendothelium is exposed to blood when blood vessels are injured, triggering the extrinsic pathway of the coagulation cascade. The half-lives of the coagulation factors in the blood vary markedly, with Factor VII showing the shortest half-life of approximately 5 hours and Factor XIII having the longest half-life of more than 120 hours. There is also a wide range of plasma concentrations for the coagulation factors. Factor VII is in the lowest concentration of the circulating coagulation factors at 100 to 500 ng/mL. The highest concentration is found for fibrinogen at 200 to 400 mg/dL.

Fibrinolysis

Fibrinolysis is the controlled dissolution of the formed clot. It occurs when the injured vessel begins to heal, and is initiated to a limited extent when clot formation begins. In this way, fibrinolysis serves as a regulatory mechanism to limit excess clot formation.

The principal enzyme involved in fibrinolysis is plasmin, which exists in a zymogen form known as plasminogen (Figure 11–4). Plasminogen is converted into plasmin by tissue plasminogen activator (tPA). Plasmin degrades the fibrin clot. A recombinant form of tPA is used as a pharmacologic agent to produce thrombolysis (breakdown of a thrombus), in patients with myocardial infarction or stroke, and clots elsewhere in the body. Clinically effective derivatives of tPA from genetic manipulation are also used for thrombolysis. tPA is released by endothelial cells, and its secretion into the plasma is increased by thrombin. Plasminogen activator inhibitors are secreted by platelets and endothelial cells, particularly when they are activated. Plasminogen activator inhibitors stabilize a newly formed clot by blocking the action of tPA, thereby preventing premature dissolution of the clot. Plasmin degrades fibrin polymers, and, to a limited degree, fibrinogen as well, by specific and sequential proteolytic cleavages, generating fibrin degradation products (FDP). These FDP (fragments X, Y, D, D-dimer, and E) may be detected in the plasma of patients experiencing fibrinolysis. Deficiency of plasminogen may predispose to thrombosis, and deficiency of plasminogen activator inhibitor may increase the risk for bleeding. Antiplasmin inhibits plasmin, but only when it is circulating and not when

![Fibrinolysis Diagram](image-url)
it is clot-bound. This prevents the circulation of a proteolytically active form of plasmin, while permitting clot lysis to proceed by plasmin within the clot. Deficiency of antiplasmin may result in a hemorrhagic tendency.

**BLEEDING DISORDERS**

Figure 11-5 provides a classification of coagulation disorders. The major division in the classification is between disorders associated with bleeding and disorders associated with thrombosis. There are 2 major subdivisions of bleeding disorders—those associated with coagulation factor and fibrinolytic pathway factor deficiencies, and those associated with an abnormal platelet count or impaired platelet function. Isolated factor deficiencies are usually congenital, although occasionally an isolated acquired factor deficiency develops. An example of an acquired isolated coagulation factor deficiency is the Factor X deficiency associated with amyloidosis. The deficiency of antiplasmin is listed in this section because its absence permits increased plasmin activity and overactive clot dissolution, resulting in a bleeding tendency. Another major category of coagulation factor abnormalities is multiple coagulation factor deficiencies. There are several commonly encountered situations associated with multiple factor deficiencies. These include vitamin K deficiency or warfarin intake (which results in a reduced amount of functional Factors II, VII, IX, and X as well as protein C and protein S); disseminated intravascular coagulation (DIC), which results in the consumption of multiple coagulation factors; and liver disease that results in decreased synthesis of coagulation factors. Several activated coagulation factors are inhibited by heparin. Heparin administration results in inactivation of most of the activated coagulation factors.

The group of disorders associated with platelets is divided first into quantitative platelet disorders and qualitative platelet disorders. Quantitative platelet disorders include thrombocytopenia and thrombocytosis. Thrombocytopenia can be produced as a result of increased platelet destruction, from a variety of immune or nonimmune causes, or decreased platelet production. Common causes of decreased platelet production include tumor infiltration of bone marrow from metastases or a hematologic malignancy, and drug-induced thrombocytopenia as occurs with chemotherapy. Thrombocytopenia can also occur as a result of increased sequestration of platelets in the spleen, usually in patients with splenomegaly. Thrombocytosis is much less common than thrombocytopenia. Thrombocytosis can be divided into reactive thrombocytosis, in which there is a transiently increased number of platelets from a stimulus to increase platelet production, or neoplastic thrombocytosis, as seen in myeloproliferative disease and, less commonly, myelodysplastic disorders.

Qualitative platelet disorders are characterized by abnormal platelet function in the presence of a normal platelet count. vWD is a disorder in which there is defective platelet function, but from a defect originating outside the platelet, since vWF is generated primarily in endothelial cells. vWF coats the surface of the activated platelet to allow it to adhere to the cut vessel surface and initiate platelet plug formation.

Other causes of defective platelet function result from abnormalities within the platelet. These disorders may be congenital or acquired. The congenital ones are extremely rare, and the acquired ones are very frequently encountered. Congenital platelet abnormalities associated with defective function include GT, Bernard–Soulier disease, and storage pool disease (SPD). The much more common acquired qualitative platelet disorders include drug-induced platelet dysfunction, such as produced by aspirin and clopidogrel (Plavix), and uremia-induced platelet dysfunction, which occurs in patients with impaired renal function.

**Fibrinogen Deficiencies**

**Description**

Fibrinogen is produced in the liver by hepatocytes. Abnormalities of fibrinogen production may be congenital or acquired and, in general, involve either decreased production of a normal molecule (afibrinogenemia and hypofibrinogenemia) or production of an abnormal molecule (dysfibrinogenemia) (see Table 11-1).
In *congenital afibrinogenemia* and *hypofibrinogenemia*, there is a reduced (hypofibrinogenemia) or absent (afibrinogenemia) production of a normal fibrinogen molecule. In general, the homozygous deficiency results in afibrinogenemia, and the heterozygous state results in hypofibrinogenemia. Both disorders are rare. Homozygotes suffer a mild-to-moderate spontaneous bleeding tendency. Manifestations include umbilical stump hemorrhage and bleeding from mucous membranes, among many other possible signs and symptoms related to blood loss. Severe bleeding may occur with trauma or surgery. Hypofibrinogenemic patients are usually asymptomatic, but may bleed significantly with surgery or trauma.

*Congenital dysfibrinogenemia* is a result of inheritance of a gene for an abnormal fibrinogen molecule, which is produced in normal or near-normal quantities. All the fibrinogen produced by a homozygote for dysfibrinogenemia is abnormal, and approximately half of the fibrinogen in a heterozygote is abnormal. Hundreds of abnormal fibrinogens have been described. The true incidence of dysfibrinogenemia is not known because many forms of the disorder are asymptomatic. Homozygotes may have a mild bleeding tendency, perhaps because the fibrinogen molecule is cleaved too slowly to form fibrin monomers or because abnormal fibrin monomers polymerize too slowly. The bleeding tendency is characterized by easy or spontaneous bruising, menorrhagia, and prolonged or severe bleeding with surgery or trauma. Heterozygotes are usually asymptomatic, but may show excessive bleeding with surgery or trauma. Several types of dysfibrinogenemia (approximately 10%-15% of cases) are associated with an increased risk of thrombosis rather than bleeding. A few types of congenital dysfibrinogenemia are associated with both bleeding and thrombosis.

*Acquired hypofibrinogenemia* is observed predominantly in patients with advanced liver disease, in patients with a consumptive coagulation disorder such as DIC, and in those treated with thrombolytic therapy.

*Acquired dysfibrinogenemia* represents the acquired production of an abnormal fibrinogen molecule in normal or near-normal quantities, most often in patients with acute or chronic liver disease, especially those with primary or metastatic hepatic malignancies. The patient may or may not be symptomatic, depending on 1) whether there is simultaneous production of normal fibrinogen in amounts sufficient to allow normal hemostasis and 2) whether the abnormal fibrinogen can polymerize like a normal fibrinogen molecule (see the section “Hemostatic Abnormalities in Liver Disease”).

### Diagnosis

See Table 11–1 for the laboratory evaluation of the patient with a fibrinogen deficiency.

Prothrombin (Factor II) Deficiency

Description
Prothrombin (Factor II) is the precursor to thrombin (Factor IIa), which converts fibrinogen into fibrin in the common pathway of the coagulation cascade. Deficiency of prothrombin, either inherited or acquired, may result in a hemorrhagic diathesis. Inherited abnormalities of prothrombin are rare. As with fibrinogen, abnormalities occur in 2 major forms. The first is reduced or absent production of a normal prothrombin molecule. The second is production of normal amounts of an abnormal prothrombin molecule with decreased activity (dysfunctional form or dysprothrombinemia). Heterozygotes usually have approximately 50% of normal activity and may be asymptomatic or have a bleeding tendency. In 1 study, 83% of a small cohort of heterozygotes had bleeding, with Factor II levels ranging from 21% to 35%. Homozygotes usually have 1% to 25% of normal activity and have a mild-to-severe hemorrhagic tendency.

Acquired hypoprothrombinemia occurs most often along with deficiencies of Factors VII, IX, and X in vitamin K deficiency and with warfarin (Coumadin) therapy; with deficiencies of multiple coagulation factors in liver disease or DIC; as an isolated coagulation factor deficiency in some patients with lupus anticoagulant (LA); and in patients exposed to topical bovine thrombin who develop antibodies to prothrombin (and not uncommonly to Factor V also). Bleeding manifestations depend on the level of prothrombin activity; usually no bleeding occurs with a prothrombin level >50% of normal.

Diagnosis
See Table 11–2 for the laboratory evaluation of the patient with a prothrombin (Factor II) deficiency.

Factor V Deficiency

Description
Factor V is a high-molecular-weight protein (approximately 300,000 Da) that acts as an accelerating cofactor for the enzymatic conversion of prothrombin to thrombin by Factor Xa. When Factor V is cleaved to Factor Va by thrombin, its cofactor activity is significantly increased. Factors Va and VIIIa are degraded by activated protein C. An isolated deficiency of Factor V is a rare cause of bleeding.

Apparent heterozygous and homozygous deficient states have been observed. Heterozygotes usually have levels of approximately 50% of normal and can experience bleeding or may be asymptomatic. In a cohort of 19 heterozygous patients, 50% had bleeding, with Factor V levels ranging from 21% to 55%. Homozygotes have variable levels below 50%; they are most likely to be symptomatic if the level is 10% or less.

As with the other coagulation factors, 2 major forms of the inherited deficiency are described: reduced or absent production of a normal Factor V molecule (absence form) and production of an abnormal molecule with reduced activity in normal amounts (dysfunctional form). A rare combined deficiency of Factors V and VIII is due to a genetic defect in intracellular transport of Factors V and VIII. Acquired deficiencies of Factor V occur with liver dysfunction or DIC.

Diagnosis
See Table 11–2 for the laboratory evaluation of the patient with a Factor V deficiency.

Factor VII Deficiency

Description
Factor VII is a vitamin K-dependent coagulation factor precursor that, when activated by thrombin, Factor Xa, or Factor IXa, is converted to Factor VIIa. This activated factor then converts phospholipid-bound Factor X into Factor Xa in the presence of calcium and tissue factor. It also converts Factor IX to Factor IXa. Factor VII deficiency may occur as an inherited or acquired disorder.
The inherited deficiency state, which is rare, may be present as reduced or absent production of a normal molecule (absence form) or production of an abnormal molecule with decreased activity in normal amounts (dysfunctional form). An inherited isolated deficiency of Factor VII in heterozygotes is usually associated with a Factor VII activity level of approximately 50%. In a cohort of 88 heterozygous patients, 36% had a bleeding tendency, with Factor VII levels ranging from 21% to 69%. In homozygotes, there are variable Factor VII activity levels below 50%. The bleeding risk is difficult to predict in these patients because the factor activity level correlates poorly with the patient's tendency to hemorrhage, but in general values <10% can be associated with major spontaneous bleeding. A large proportion of patients with less than 2% Factor VII do not bleed. Acquired Factor VII deficiency occurs in vitamin K deficiency and with warfarin therapy along with deficiencies of Factors II, IX, and X; and in DIC or liver disease along with multiple other coagulation factor deficiencies.

Intracranial hemorrhage has been reported in Factor VII-deficient patients, most often occurring in infants <1 year of age. Elevated Factor VII levels have been associated with an increased risk of cardiovascular disease.

**Diagnosis**

See Table 11–2 for the laboratory evaluation of the patient with a Factor VII deficiency.
Hemophilia A (Factor VIII Deficiency)

Description
Hemophilia A is a bleeding disorder resulting from a deficiency of Factor VIII procoagulant activity. Factor VIII circulates in the plasma bound to vWF. Approximately 90% of patients with hemophilia A synthesize low amounts of normal Factor VIII molecules, and 10% of patients with hemophilia A synthesize normal amounts of an abnormal (nonfunctional) Factor VIII. Hemophilia A is inherited as an X-linked trait, and 65% to 75% of patients have a positive family history. Disease prevalence in the United States is 1 in 10,000 males; the carrier state in females is rarely symptomatic. Hemophilia A and hemophilia B (Factor IX deficiency, see below) are clinically indistinguishable. The likelihood of hemorrhage depends on the amount of Factor VIII present; the majority of patients (approximately 50%-70% of hemophilia A patients) have severe disease. The severity of disease is categorized as follows:

- In mild disease: the VIII level is 6% to 20% of normal, with rare spontaneous bleeding.
- In moderate disease: the VIII level is 1% to 5% of normal, with occasional spontaneous bleeding.
- In severe disease: the VIII level is <1% of normal, with frequent spontaneous bleeding.

All hemophilia patients (A and B) may experience severe hemorrhage following trauma or surgery if there is no prior treatment to elevate the factor level. Bleeding that is characteristic of hemophilia (A and B) includes intra-articular (joint), intracranial, and intramuscular hemorrhage. The latter can produce a compartment compression syndrome. Easy bruising and prolonged bleeding after minor cuts and abrasions are also characteristic. The onset of hemorrhage is typically delayed following injury, and pathologic bleeding may occur hours after injury. Primary hemostasis (dependent on platelet plug formation) is intact, but secondary hemostasis (dependent on the fibrin clot generated by the coagulation cascade) is defective. Up to 15% of hemophilia A patients develop an inhibitor to Factor VIII at some time during the course of their disease (ie, an antibody against Factor VIII). The inhibitor develops only in those transfused with Factor VIII-containing products, and most often in patients with <1% Factor VIII. Factor VIII inhibitors may also spontaneously occur rarely in nonhemophiliacs (see the section “Factor VIII Inhibitors”).

Diagnosis
See Table 11–2 for information regarding the laboratory evaluation for Factor VIII deficiency.

Factor VIII Inhibitors

Description
Factor VIII inhibitors are antibodies, usually IgG, that bind to Factor VIII and inhibit its coagulant activity.

Factor VIII inhibitors have been found in several clinical situations.

- Inhibitors are diagnosed most commonly in patients with hemophilia A. Inhibitors occur in 10% to 15% of these patients and make the treatment of hemorrhage much more difficult. The vast majority of cases of Factor VIII inhibitors in hemophilia A patients occur in those with severe hemophilia A (<1% Factor VIII activity). Inhibitor formation is related to transfusion of exogenous Factor VIII, and usually develops before 100 treatment days if it appears. Two immune response patterns have been observed in hemophilia A patients. The first is a high response pattern. Inhibitors rise to a high titer in response to exposure to Factor VIII. The titer may not decline for months to years, even without further exposure to Factor VIII. Rapid anamnestic responses are often seen within 3 to 7 days of reexposure in these patients. In the second pattern, there is a low response. In addition, inhibitors usually remain at a low titer despite reexposure. They may occasionally disappear and reappear spontaneously. Little, if any, anamnestic response is likely found in a low responder.
- Spontaneous inhibitors to Factor VIII can occur in the postpartum patient. Usually they are recognized 2 to 5 months after the birth of the first child and disappear spontaneously.
after 12 to 18 months. However, the course is variable, and there are reports of death from hemorrhage in some patients. Antigenic differences between mother and fetus do not sufficiently explain the development of a Factor VIII inhibitor, and its cause remains unknown.

- Inhibitors may occur in those with allergic and enhanced immunologic reactions, including patients with:
  - Rheumatoid arthritis
  - Systemic lupus erythematosus
  - Reactions to drugs, such as penicillin, chloramphenicol, sulfonamides, and phenytoin
  - Malignancy
  - Asthma
  - Crohn disease
  - Ulcerative colitis
  - Pemphigus
  - Multiple myeloma

- Inhibitors may appear in patients without any obvious underlying disorder. These are usually older individuals, and the inhibitor may remit in several months, persist for years, or disappear with immunosuppressive therapy.

In a hemophilia A patient, a poor response to treatment with Factor VIII concentrate may be the first indication that an inhibitor is present, or there may be an increased frequency of bleeding episodes. In nonhemophiliacs, development of a new hemorrhagic tendency is usually the presenting feature of a spontaneous Factor VIII inhibitor. The most favorable prognoses are for patients with low titer inhibitors, peripartum women, and patients without an underlying disorder.

### Diagnosis

See Table 11–3 for information regarding the laboratory evaluation for a Factor VIII inhibitor.

### Hemophilia B (Factor IX Deficiency)

#### Description

Hemophilia B is an inherited hemorrhagic disorder resulting from a lack of procoagulant activity of Factor IX. Factor IX is a vitamin K-dependent factor that, in its active form (Factor IXa), is a serine protease of the intrinsic pathway of the coagulation cascade. Approximately 70% to 90% of hemophilia B patients have a deficiency of a normal coagulant protein, and 10% to 30% produce an abnormal Factor IX that is nonfunctional. Inheritance is sex-linked, with affected males, and female carriers. Of hemophilia B patients, 60% to 70% have a positive family history for bleeding. The prevalence of hemophilia B is much less than that of hemophilia A. Approximately 1 in

*PT, prothrombin time; PTT, partial thromboplastin time.*
50,000 males in the United States has hemophilia B versus 1 in 10,000 males with hemophilia A. The hemophilia B carrier state in the female is usually asymptomatic, as is the case with hemophilia A. Acquired Factor IX deficiency may occur along with deficiencies of Factors II, VII, and X in patients with vitamin K deficiency or those receiving warfarin therapy, and with deficiencies of other coagulation factors in patients with liver disease, DIC, or nephrotic syndrome.

As previously noted, hemophilia B is clinically indistinguishable from hemophilia A. The severity of hemorrhage depends on the amount of Factor IX activity present:

- In mild disease: 6% to 20% of normal IX activity is present, with rare spontaneous bleeding.
- In moderate disease: 1% to 5% of normal IX activity is present, with occasional spontaneous bleeding.
- In severe disease: <1% of normal activity is present, with frequent spontaneous bleeding.

Profuse bleeding may occur in any hemophilia B patient with trauma or surgery if there is no prior treatment to elevate the factor level. Bleeding in hemophilia B resembles that found in hemophilia A and includes deep tissue bleeding, intra-articular bleeding (hemarthrosis), intracranial bleeding (which may be lethal), and intramuscular bleeding with potential compartment compression syndrome. Severe mucosal membrane bleeding can occur in hemophilia, particularly after dental surgery.

Inhibitors develop to Factor IX in 1% to 5% of hemophilia B cases. These antibodies often occur in high titer and frequently present a major bleeding problem despite treatment.

**Diagnosis**

See Table 11–2 for information regarding the laboratory evaluation for patients with hemophilia B.

**Factor X Deficiency**

**Description**

An inherited isolated deficiency of Factor X is a rare disorder. Homozygotes and heterozygotes have been identified. Homozygotes usually possess <2% of normal activity. Heterozygotes usually possess 40% to 70% of normal activity. In a cohort of 15 heterozygous patients, 33% had a bleeding tendency, with Factor X levels ranging from 23% to 47%. Patients with Factor X values <10% can have a high risk of spontaneous major bleeding, and those with >40% are usually asymptomatic. Inherited Factor X deficiency, like the other factor deficiency states, occurs in 2 major forms: reduced or absent synthesis of a normal molecule (absence form) and synthesis of an abnormal molecule in normal amounts (dysfunctional form).

Acquired Factor X deficiency may result from warfarin or vitamin K deficiency (in the presence of deficiencies of Factors II, VII, and IX), from liver disease (with deficiencies of other factors synthesized in the liver), with DIC, or as an isolated deficiency in cases of amyloidosis. In amyloidosis, Factor X becomes irreversibly bound to amyloid fibrils in the extracellular space, and is thereby removed from the circulation.

**Diagnosis**

See Table 11–2 for information regarding the laboratory evaluation of patients with Factor X deficiency.

**Factor XI Deficiency**

**Description**

Factor XI deficiency is a commonly encountered disorder. Homozygotes typically have less than 20% of normal Factor XI activity. Heterozygotes have 20% to 70% of normal Factor XI activity. The deficiency in almost all cases appears to be a reduced or absent production of a normal molecule, rather than production of an abnormal or dysfunctional molecule.

The vast majority of the cases of Factor XI deficiency are in people of Jewish descent, particularly those of Ashkenazi origin. The frequency of the homozygous deficient state is 0.2% to
0.3% in the Ashkenazi population, and the frequency of the heterozygous state is extremely high, at approximately 5.5% to 11.0%.

The hemorrhagic tendency is variable for both heterozygotes and homozygotes. Patients with Factor XI levels <15% to 20% uncommonly have spontaneous bleeding but frequently have postoperative bleeding, and patients with levels between 20% and 65% tend to be asymptomatic or have low rates of postoperative bleeding. Bleeding does not correlate well with the level of Factor XI activity. Some homozygotes have an abnormal partial thromboplastin time (PTT), a very low Factor XI level of less than 10%, and no bleeding, even with surgery. The bleeding tendency of a particular individual is more closely related to the bleeding tendency of the patient’s kindred than to the measured Factor XI level. The explanation, which is true for all mutations affecting coagulation factors, is that certain mutations produce a low level of Factor XI and a prolonged PTT but are not clinically significant in vivo. This is because they only affect the activity of the factor in the in vitro clotting factor assays, which are not exact replicas of clot formation in vivo. Acquired decreases in Factor XI can occur with pregnancy, proteinuria, liver dysfunction, and DIC.

Diagnosis
See Table 11–2 for information regarding the laboratory evaluation of patients with Factor XI deficiency.

Deficiencies of the Contact Factors
Description
The contact coagulation factors (so named because they were originally thought to activate the coagulation cascade by contacting the cut surface of the vessel wall) include Factor XII, PK, and HMWK. A deficiency of any of the contact factors prolongs the PTT because the PTT assay is constructed to involve these factors, even though the coagulation cascade in vivo does not depend on these factors. Bleeding diatheses have not been reported in patients with deficiencies at any level of Factor XII, PK, or HMWK. Factor XII deficiency is fairly common, with many thousands affected, especially individuals of Asian descent and children with tonsillitis. HMWK deficiency and PK deficiency are rare.

Diagnosis
See Table 11–2 for information regarding the laboratory evaluation for contact factor abnormalities.

Factor XIII Deficiency
Description
Factor XIII circulates in plasma as a zymogen and is converted to its active form (Factor XIIIa) by thrombin. Factor XIIIa catalyzes the formation of covalent bonds between chains of adjacent fibrin monomers. This stabilizes the fibrin clot, making it rigid and more resistant to the action of plasmin. Congenital deficiency of Factor XIII is rare. The bleeding tendency in homozygotes is characterized by umbilical stump bleeding in newborns (>90% of patients with clinically significant Factor XIII deficiency have this finding), intracranial hemorrhage, miscarriages, and posttraumatic hematomas, with bleeding often delayed hours to days after the trauma. Patients with mild or moderate deficiencies might have mucocutaneous bleeding or be asymptomatic. Patients with Factor XIII levels above 30% are usually always asymptomatic.

Diagnosis
See Table 11–2 for information regarding the laboratory evaluation for Factor XIII deficiency.

Antiplasmin Deficiency
Description
Antiplasmin or plasmin inhibitor (formerly known as alpha-2 antiplasmin) is a glycoprotein (GP) that serves as a regulator of fibrinolysis in several ways (see Figure 11–4). It blocks the
enzymatic activity of plasmin (the major fibrinolytic enzyme) and other serine proteases, some of which are coagulation factors, and it inhibits the binding of plasminogen to fibrin. A bleeding diathesis is associated with the congenital deficiency of plasmin inhibitor. It is an extremely rare disorder and only homozygotes with <10% of normal plasmin inhibitor activity appear to be clinically affected. Those who do bleed may experience mucosal membrane bleeding (particularly in the genitourinary tract), subcutaneous hematomas, spontaneous bruising, and severe bleeding with trauma. Most heterozygotes are asymptomatic, but those few who are symptomatic have only a mild bleeding tendency. Acquired deficiency of plasmin inhibitor can occur in liver disease, nephrotic syndrome, amyloidosis, DIC, and, most notably, following thrombolytic therapy. In thrombolytic therapy, plasminogen is purposefully converted to plasmin, which results in the formation of plasmin–antiplasmin complexes, thereby reducing the amount of available antiplasmin.

Diagnosis
See Table 11–4 for information on the laboratory evaluation of plasmin inhibitor deficiency.

### Vitamin K Deficiency

#### Description
In adults, vitamin K deficiency most often occurs secondary to disease or drug therapy; it rarely occurs as a dietary deficiency. Causes of vitamin K deficiency include:

- Warfarin therapy (reduces the amount of active vitamin K)
- Antibiotic therapy (capable of suppressing bowel flora that synthesize vitamin K)
- Malabsorption syndromes: cystic fibrosis, sprue, ulcerative colitis, Crohn disease, parasitic infections, short bowel syndrome, and ileojejunostomy (for morbid obesity)
- Dietary restriction with incidental decrease in vitamin K intake
- Long-term total parenteral nutrition
- Biliary obstruction

Vitamin K depletion can occur in as little as 2 weeks if both intake (enteral and parenteral) and endogenous production of vitamin K are eliminated. In early deficiency, Factor VII only, or Factors VII and IX only, may be decreased due to their shorter half-lives. Vitamin K deficiency may present as an asymptomatic prolongation of the PT in mild cases or as a major spontaneous hemorrhage in severe deficiencies. The degree of prolongation of the PT does not accurately predict the risk of hemorrhage.

Most antibiotics destroy bacterial flora and must be considered as a possible cause of vitamin K deficiency in the bleeding patient. However, certain cephalosporins produce vitamin K deficiency much more rapidly than other antibiotics. Cephalosporins with an N-methylthiotetrazole (MTT) group in position 3 directly inhibit the vitamin K-dependent carboxylase that is responsible for converting Factors II, VII, IX, and X to their active form. Cephalosporins in the MTT group include cefamandole, cefoperazone, cefotetan, moxalactam, cefmetazole, and cefmenoxime. Weekly prophylaxis with vitamin K has been recommended when MTT-cephalosporins are given to patients at high risk for vitamin K deficiency.

Disseminated Intravascular Coagulation

Description
DIC is a common acquired coagulation disorder that occurs secondary to a variety of underlying disorders. The most common cause is infection; 10% to 20% of patients with gram-negative sepsis develop DIC. Other causes of DIC include obstetrical complications (retained dead fetus, placental abruption, amniotic fluid embolism, hypertonic saline-induced abortion, and septic abortion), extensive tissue injury (including trauma, ischemia, infarction, and burns), liver disease, transfusion of ABO-incompatible blood, and adult respiratory distress syndrome. The clinical presentation varies from an asymptomatic condition, detectable only by laboratory abnormalities, to a severe coagulopathy with a mortality of up to 80%.

The major events in acute DIC, independent of the cause, are microvascular thrombosis with consumption of platelets and coagulation factors, and then hemorrhage as a result of low levels of platelets and coagulation factors and overactivation of the fibrinolytic system to remove the thrombi. Hemorrhagic symptoms can include any of the following—petechiae, ecchymoses, mucosal oozing, hematuria, gastrointestinal tract bleeding, bleeding into surgical wounds, and prolonged bleeding at venous access sites. Severe bleeding may contribute to hypotensive shock.

DIC may present as a more chronic, low-grade condition in patients with malignancy. These patients are at risk for macrovascular (large vessel) thrombosis as well, most likely as a deep vein thrombosis.

The prolongations of the PT and the PTT reflect a decrease in fibrinogen and other coagulation factors that are consumed by clotting. In addition, fibrinogen is degraded by excess plasmin activation in the fibrinolytic system. Platelets are also consumed, and, therefore, the platelet count is typically low. The presence of FDP, 1 of which is the D-dimer, indicates that fibrin clots have been formed and subsequently degraded. There is no single laboratory test that can diagnose or exclude DIC, and the diagnosis is made when the characteristic laboratory abnormalities are present along with a known stimulus for DIC. A practical approach to diagnosis of DIC is to perform the PT, the PTT, and a D-dimer assay, with serial measurements of fibrinogen and platelets. In severe acute DIC, most of the laboratory test results will be abnormal, although fibrinogen may be normal or even elevated. In chronic DIC, the laboratory abnormalities may be less pronounced or even absent because the liver and bone marrow can increase production of coagulation factors and platelets, respectively, to offset the losses from consumption.

Diagnosis
See Table 11–6 for information on the laboratory evaluation for DIC.
Hemostatic Abnormalities in Liver Disease

Description

Patients with acute and chronic liver disease often have laboratory evidence of a hemostatic abnormality. These patients may be asymptomatic or have only mild bleeding problems, but those with advanced liver disease may experience a severe hemorrhage.

Hemorrhage in patients with liver disease may be due to 1 or more of the following:

- Coagulation factor abnormalities: These are caused by decreased hepatic synthesis of vitamin K-dependent factors (II, VII, IX, and X) and non-vitamin K-dependent factors. Decreased fibrinogen is usually found only in patients with severe hepatic failure; in fact, patients with acute hepatitis without hepatic failure usually have an increased fibrinogen level.
- Thrombocytopenia: This frequently occurs as a consequence of sequestration in the spleen, impaired platelet production, or increased platelet destruction. It is not usually a severe decrease in platelet number.
- Platelet dysfunction: The dysfunction is usually mild and its clinical significance is uncertain; platelet dysfunction may be clinically important only in liver disease patients with severe thrombocytopenia or severe renal failure, which can result in uremia-induced platelet dysfunction.
- DIC or a DIC-like syndrome: There is no general agreement as to whether the coagulation abnormalities that occur in patients with liver disease are due to DIC, liver disease alone, or a combination of these and other mechanisms. A DIC-like syndrome occurs frequently in patients with acute hepatic failure. Laboratory abnormalities in these cases include hypofibrinogenemia, thrombocytopenia, increased FDP such as D-dimer, and decreased levels of Factors V and VIII.
- Acquired dysfibrinogenemia (in patients with selected liver diseases [see the section “Fibrinogen Deficiencies”]): Impaired fibrin polymerization may result and thereby predispose the patient to bleeding.
- Increased fibrinolysis: Hemostatic abnormalities in patients with cirrhosis may be due to increased fibrinolysis. This may occur as a result of decreased hepatic clearance of plasminogen activators and decreased synthesis of inhibitors of fibrinolysis (see Figure 11–4).
Diagnosis

The laboratory evaluation for hemostatic defects from liver disease is shown in Table 11–7.

### Immune Thrombocytopenic Purpura (ITP)

**Description**

ITP (where the I formerly stood for idiopathic) exists in both an acute and a chronic form. The disorder is one in which accelerated platelet destruction occurs in the absence of other causes such as DIC, thrombotic thrombocytopenic purpura (TTP), drug-induced thrombocytopenia, and neonatal thrombocytopenia. Platelet production is also often reduced.

The destruction of platelets in ITP is antibody-mediated. The amount of platelet-associated IgG is increased in the majority of patients with acute and chronic ITP. Many patients with chronic ITP have increased levels of antiplatelet antibodies in the serum, as well as on the platelet surface. It should be noted that there are a host of disorders unrelated to immune thrombocytopenias, which are associated with increased IgG on the platelet surface. *Helicobacter pylori* infection has been associated with ITP.

In acute ITP, the platelet may be an innocent target of an antipathogen antibody that cross-reacts with an epitope on the platelet membrane. Chronic ITP appears to be more of a classic autoimmune illness in which the target antigens for platelet autoantibodies are platelet GPs. Sequestration and destruction of antibody-coated platelets occur predominantly in the spleen.

Acute ITP usually presents as a childhood illness with peak incidence between 2 and 9 years. It is heralded by a prodromal illness, such as a viral respiratory infection, in 60% to 80% of cases. The infection occurs 2 to 21 days prior to onset of thrombocytopenia. The risk of hemorrhage is greatest during the first 1 to 2 weeks after the onset of acute ITP. Intracranial hemorrhage is the most feared complication of ITP. The majority of patients experience a spontaneous resolution of acute ITP 3 weeks to 3 months after onset. A small percentage of patients do not recover fully after 12 months, and advance to a diagnosis of chronic ITP.

Chronic ITP occurs most commonly between the ages of 20 and 50 years, and in females more often than in males (ratio of 2:1 to 3:1). It is characterized by the absence of a prodromal illness and the presence of mild bleeding that may continue for months before medical attention is sought. Manifestations include scattered petechiae or purpura, mostly on distal extremities, mild mucosal bleeding, easy bruising, epistaxis, and menorrhagia. ITP is often discovered in an asymptomatic patient found to have a low platelet count as part of a complete blood count (CBC). The diagnosis of ITP is made only after ruling out other causes for an isolated thrombocytopenia by history, physical examination, and laboratory studies.

**Diagnosis**

See Table 11–8 for information on the laboratory evaluation for ITP.

**Drug-induced Immunologic Thrombocytopenia**

**Description**

Many drugs have been implicated in drug-induced immune thrombocytopenia. However, most cases can be attributed to relatively few drugs, notably heparin, quinidine/quinine, gold salts, and sulfonamides. Exposure to most of these compounds is readily ascertained. However, when obtaining the patient’s history, one should include inquiries regarding consumption of over-the-counter medications and topical medications, as well as soft drinks, mixers, and aperitifs to rule out exposure to quinine. The pathogenesis of thrombocytopenia for most drugs involves both the drug and IgG (as the predominant class of antibody involved). A plasma protein bound to the drug serves as the antigen; the antigen combines with a specific antibody, and this complex binds to the platelet membrane. This is known as an “innocent bystander” effect. The antibody-coated platelet is then sequestered and destroyed. Certain other drugs (eg, protamine, bleomycin, and ristocetin) can cause destruction of platelets by a direct toxic effect that is nonimmune. In heparin-induced thrombocytopenia (HIT), a complex of heparin and a circulating protein derived from the platelet, known as platelet factor 4 (PF4), acts as the antigen. The complex, along with bound antibody, binds to the platelet surface, causing platelet activation, and unlike other drug-induced thrombocytopenias, an increased risk for thrombosis.

The true incidence of drug-induced immunologic thrombocytopenia is not known. The incidence varies with the drug in question and the clinical condition or treatment of the patient. It may be as high as 1% to 3% of people exposed to the drug, as is the case with unfractionated (standard) heparin. Of quinidine users, approximately 1 in 1000 develop symptomatic thrombocytopenia. Drug-induced immunologic thrombocytopenia occurs most commonly in patients more than 50 years old, but it also has been reported in infants less than 1 year old. It is not possible to predict that patients will develop thrombocytopenia from drug treatment.
Ingestion of a drug that induces thrombocytopenia may produce flushing, fever, headache, and chills prior to onset of thrombocytopenia. The onset of thrombocytopenia may be abrupt following drug exposure or, if it requires antibody generation to lower the platelet count, it may be delayed for 4 to 15 days. Anamnestic responses may occur and if they arise, the delay is shorter. Bleeding may occur as early as 6 to 12 hours after exposure to the drug in highly responsive patients. Bleeding manifestations may include 1 or more of the following: petechiae, purpura (usually the first symptom), mucosal hemorrhagic bullae, gastrointestinal or genitourinary hemorrhage, intrapulmonary hemorrhage, and, lastly, intracranial hemorrhage, which is rare, but often lethal. HIT is unique in that bleeding is uncommon, and, as noted above, HIT patients are at risk for thrombosis rather than bleeding.

### Diagnosis

See Table 11–9 for information on the laboratory evaluation for drug-induced immunologic thrombocytopenia. Laboratory tests for drug-induced thrombocytopenia are not routinely available, with the exception of testing for HIT. If HIT is considered, a platelet count should be performed first. If the platelet count decreases to 50% or less of its apparent baseline value, a test for antibodies to the heparin–PF4 complex or a functional test that shows platelet activation in the presence of heparin and the patient’s plasma should be performed.

### Posttransfusion Purpura

#### Description

Posttransfusion purpura (PTP) is a rare syndrome characterized by the sudden onset of thrombocytopenia 7 to 10 days following transfusion of blood or blood products containing platelets or platelet material. The thrombocytopenia appears to be due to antibody-mediated destruction of autologous as well as transfused platelets. In over 90% of cases, the antibody that develops in the affected individuals is directed against the antigen HPA-1a, formerly known as P1A1, on platelet membrane GP IIa. In these cases, the recipient’s own platelets are HPA-1a negative. It is not known why there is destruction of the patient’s own HPA-1a-negative platelets following platelet transfusion with HPA-1a-positive platelets. Only 2% to 3% of the population in the United States lacks this antigen. Antibodies against other platelet-specific antigens have been reported in PTP, but they are much less commonly encountered. In almost all cases, the development of anti-HPA-1a antibody is thought to be an anamnestic response, with prior sensitization occurring through previous transfusion or pregnancy.

PTP occurs predominantly in females, perhaps due to the likelihood of sensitization through pregnancy. The interval between the first exposure to the HPA-1a antigen and the transfusion

<td>Tests for drug-dependent antibodies bound to the platelet and for drug-dependent antiplatelet antibodies in the serum unbound to platelets</td>
<td>Not routinely available (except for HIT antibody testing). Both test results are usually positive; however, they may be negative if the reaction is dependent on an in vivo drug metabolite, rather than the parent drug if only the parent drug is used in the laboratory test; an assay for platelet activation by the drug should be positive if the mechanism of thrombocytopenia, in the presence of the drug, includes activation of platelets by antigen–antibody complexes; an in vivo challenge with the suspected drug to confirm toxicity can be extremely dangerous and is rarely, if ever, indicated; there are a variety of methodologies for tests assessing drug-induced platelet activation, including flow cytometry and the measurement of serotonin released from activated platelets; an ELISA assay for HIT detects antibodies to heparin–platelet factor 4 complexes</td>
</tr>
</tbody>
</table>

HIT, heparin-induced thrombocytopenia.
CHAPTER 11  Bleeding and Thrombotic Disorders

that incites the thrombocytopenia is greater than 3 years in most cases in which the information has been reported. The onset of thrombocytopenia is fulminant in most cases, with the platelet count decreasing to \(<10,000/\mu L\). Hemorrhage usually begins with purpura and mucocutaneous bleeding, and may progress to gastrointestinal and genitourinary bleeding, epistaxis, oozing from intravenous access sites, and intracranial hemorrhage. In severely affected patients sustained with supportive therapy of red blood cells and/or platelets, the thrombocytopenia usually begins to resolve in 14 days (mean value with a range 1-35 days). Cases with less severe thrombocytopenia apparently require a longer recovery period (24 days average, range 6-70 days). The outcome is fatal in approximately 10% of cases, usually due to hemorrhage. The risk of fatal hemorrhage appears to be greatest at the onset of the disease. Recurrent PTP has been documented, with the recurrence appearing no sooner than 3 years after the first episode, even though antibody may persist in the patient's blood during the intervening time and there may be repeated challenges with exogenous platelets.

**Diagnosis**

See Table 11–10 for information on the laboratory evaluation for PTP.

**Neonatal Alloimmune Thrombocytopenia (NAIT)**

**Description**

NAIT is a disorder in which there is destruction of platelets in the fetus and newborn. The destruction occurs following transplacental passage of maternal IgG antibodies directed against a platelet-specific antigen present on fetal platelets and absent from the mother's platelets. The antibody-coated platelets are removed from the circulation by the neonate's reticuloendothelial system around the time of birth. The estimated incidence ranges from 1 in 5000 to 1 in 2000 births, with an increasingly higher incidence in recent years attributed to improved surveillance and serologic testing for the disorder. The platelet-specific antigen implicated in 80% to 90% of all cases (and 95% of symptomatic cases) of NAIT is HPA-1a. As previously noted, this antigen is present on the platelets of 97% to 98% of the general population. In approximately 50% of cases, NAIT occurs during the first pregnancy; when it does occur, there is a 97% chance that the next pregnancy will be affected.

Affected newborns are usually the product of an otherwise uncomplicated pregnancy and delivery. Within hours after birth, petechiae and ecchymoses appear in a generalized distribution. Other clinical signs include neurologic abnormalities if intracranial hemorrhage occurs, and pallor from anemia, if the bleeding is severe. Intracranial hemorrhage is the leading cause of death in NAIT, with a 50% mortality. Overall mortality from NAIT is approximately 5% to 10%. Thrombocytopenia usually persists for approximately 2 weeks in untreated cases (range of 1 week to 2 months), and 1 week in treated cases.

**Diagnosis**

See Table 11–11 for information on the laboratory evaluation for NAIT.
Essential Thrombocythemia

Description
Essential thrombocythemia is a chronic myeloproliferative disorder, characterized by thrombocytosis arising from the clonal proliferation of a neoplastic multipotent stem cell. Life expectancy can be essentially normal with a median survival of 10 to 15 years, but the disease course is frequently complicated by both hemorrhage and thrombosis. A small percentage (<5%) of patients progress to acute leukemia, predominantly those patients previously treated with radioactive phosphorus or alkylating agents to reduce their platelet counts. At the time of diagnosis using older criteria, mild splenomegaly occurs in 30% to 50% of patients, and hepatomegaly in 15% to 20%. Using 2008 WHO diagnostic criteria, splenomegaly is present in only a minority of patients at diagnosis. The incidence of the disorder is higher in older age groups.

The principal diagnostic feature of essential thrombocythemia is a persistently elevated platelet count with bone marrow megakaryocyte hyperplasia. Patients with this disorder can progress to a “spent” phase, characterized by myelofibrosis and a low platelet count. The purpose of the laboratory testing is to eliminate other possible etiologies for the thrombocytosis. Other entities in the differential diagnosis of an elevated platelet count include reactive thrombocytosis and other myeloproliferative disorders—myelofibrosis, polycythemia vera, and chronic myelogenous leukemia.

Diagnosis
See Table 11–12 for information on the laboratory evaluation for essential thrombocythemia.

von Willebrand Disease

Description
vWD is caused by a quantitative deficiency of normal vWF in the majority of cases and a qualitatively abnormal vWF in the remainder of cases. vWF normally polymerizes to form multimers, which are aggregates of a single vWF polypeptide; in normal plasma, the multimers have a range of sizes. vWF has 2 major roles:

- Platelet adhesion: Large multimers of vWF (i.e., those with many units of the single polypeptide) effectively promote platelet adhesion to the subendothelium in injured vessels; if only small multimers are present, platelet plugs form poorly.
- Binding of Factor VIII: vWF circulates in the plasma with Factor VIII, the coagulant protein that is lacking in hemophilia A. vWF prolongs the half-life of Factor VIII by protecting it from rapid degradation. If vWF is reduced, Factor VIII coagulant activity is often reduced as well.

<td>Acquired vWD: Reduction in plasma vWF associated with the presence of an underlying disease that leads to removal of vWF from the circulation</td>
</tr>
</tbody>
</table>

vWD prevalence estimates vary, with reported values as high as 1% of the general population. Unlike hemophilia A and B, vWD affects both men and women. It is likely to be the most common inherited bleeding disorder. There are 3 major types of vWD. The types were reorganized and renumbered with Arabic numerals in the 1990s (see Table 11–13). The most common type (type 1) is usually a mild bleeding disorder; it accounts for the majority of all cases of vWD. Type 2 vWD includes patients with qualitative vWF defects. Type 3 is rare and inherited as an autosomal recessive trait. It is associated with severe bleeding and very low to absent vWF levels. The types are distinguished from each other by laboratory testing.

PTT, partial thromboplastin time; vWF, von Willebrand factor.

It should also be noted that the mean vWF levels vary with blood type as shown in the second portion of Table 11–14.

More than 65% of patients with vWD have type O, presumably because patients with this blood type start from a lower baseline value for vWF.

The severity of bleeding is highly variable among patients, even within the same subtype of vWD, and even within an individual patient over time. Typically, bleeding manifestations such as easy bruising or epistaxis begin in early childhood. Other manifestations include menorrhagia and mucous membrane bleeding (from the gingiva, oropharynx, and gastrointestinal and genitourinary tracts). Profuse hemorrhage may occur with a significant hemostatic challenge such as trauma or surgery.

**Diagnosis**

Laboratory test results vary with the type and subtype of vWD. Like the severity of bleeding, the laboratory values can also vary widely over time for an individual patient, and may sometimes be normal. Normal results from a single determination do not rule out the diagnosis. If the patient history strongly suggests vWD, and the test results are normal, the tests should be repeated at a later time because plasma levels for vWF are increased during pregnancy, stress, while receiving oral contraceptives, and during an acute illness or injury. Therefore, values obtained at these times may be unreliable for diagnosis. It is also not yet clear if the absolute level of vWF or the level relative to the mean vWF for the blood type of the patient is more important in establishing the diagnosis. Current guidelines note that the absolute level of vWF seems to be more important than the level relative to blood type.

See Table 11–14 for information on the laboratory evaluation for vWD.

**von Willebrand Disease Types, Subtypes, and Their Expected Test Results**

- Type 1: vWF multimers of all sizes are decreased due to a defect in synthesis or release of vWF from the endothelium, the site of most vWF synthesis. Functional (ristocetin cofactor or vWF:RCo) and antigenic (vWF antigen or vWF:Ag) levels of vWF are usually proportionately decreased. Factor VIII activity might also be low. The vWF multimer pattern shows a normal distribution of multimers.
Type 2A: Absence of large and intermediate-size vWF multimers from the plasma and platelet surface, due to a defect in the synthesis or polymerization of multimers, or from increased proteolysis of multimers. Functional activity (vWF:RCo) is decreased compared with antigenic levels (vWF:Ag). Therefore, vWF:RCo < vWF:Ag < Factor VIII is the most commonly observed pattern in type 2A. The vWF multimer pattern shows an abnormal distribution of multimers, with the absence of large and intermediate-size multimers.

Type 2B: Marked deficiency of large vWF multimers from plasma. Intermediate-size and small multimers are present. Large multimers are present on the patient’s platelets, due to increased affinity of the abnormal vWF molecule for the platelet surface. Functional and antigenic levels in plasma samples are similar to those in type 2A (vWF:RCo < vWF:Ag < Factor VIII). The vWF multimer pattern shows the absence of large multimers from plasma. The patient’s platelets show increased aggregation at low concentrations of ristocetin that do not cause normal platelets to aggregate. The patient’s platelets aggregate at low concentrations of ristocetin because they are coated with large vWF multimers.

Types 2M and 2N are uncommon and are briefly described in Table 11–13.

Type 3: Severe deficiency of all vWF multimers, due to a marked defect in synthesis. Factor VIII activity is less severely affected than vWF activity. Both functional and antigenic vWF levels are markedly reduced. The vWF multimer pattern shows a virtual absence of all-size multimers.

Platelet-type Willebrand disease: vWF is qualitatively normal, but abnormal platelets have an increased affinity for large multimers of vWF due to a defect in platelet GP Ib. The laboratory test values are similar to those in type 2B.

Acquired vWD: This disorder has been found in patients with systemic lupus erythematosus, multiple myeloma, Waldenström macroglobulinemia, lymphoproliferative disorders, and other diseases. Patients have no congenital or familial history of bleeding. Causes of the decrease in circulating vWF include adsorption of large multimers onto cells (eg, lymphocytes or tumor cells) or the presence of antibodies to vWF. Acquired vWD resolves when the underlying disorder is effectively treated.

Bernard–Soulier Disease and Glanzmann Thrombasthenia

Description
Bernard–Soulier syndrome (BS) and GT are rare congenital hemorrhagic disorders that result from absent or defective specific platelet membrane glycoproteins, impairing platelet function. BS is characterized by a decrease of functional GP Ib/IX/V, the platelet receptor for vWF. GT is characterized by a decrease of functional GP IIb/IIIa, the complex that mediates platelet aggregation by binding fibrinogen to the platelet surface when platelets are activated. GT often decreases in severity with age. Manifestations include easy bruising, epistaxis, mucous membrane bleeding—particularly in the gastrointestinal tract—and menorrhagia. The amount of hemorrhage is highly variable among affected patients.

Diagnosis
See Table 11–15 for information on the laboratory evaluation for BS and GT.

Platelet Storage Pool Disease

Description
Platelet SPD represents a group of disorders in which there is a deficiency of platelet granules. Decreased secretion of platelet granular contents at the time of platelet activation makes the platelets less hemostatically effective. The congenital forms of SPD include:

- Delta SPD: platelets have a decreased number of delta (dense) granules; these secretory granules contain ADP, polyphosphate, serotonin, and calcium.
- Alpha-delta or alpha-partial delta SPD: decreased number of delta granules with either a complete or partial deficiency of alpha granules; alpha granules contain many proteins including fibrinogen, PF4, platelet-derived growth factor, and beta-thromboglobulin.
• Alpha SPD ("gray platelet syndrome"): decreased number of alpha granules, and a normal number of delta granules; platelets appear gray, large, and vacuolated on a peripheral blood smear.

SPD also may occur as an acquired abnormality, acutely in patients who have been supported on a cardiopulmonary bypass device and chronically in some cases of acute leukemia and myeloproliferative disorders. The molecular basis of most types of congenital SPD is unknown. It may result from abnormal granule morphogenesis or abnormal granule maturation in megakaryocytes. SPD may be a manifestation of a global defect in granule formation as in the Hermansky–Pudlak syndrome (see below). Hereditary SPD is the most common congenital qualitative platelet disorder, but it is still quite rare.

Most patients with SPD have mild bleeding symptoms. Bleeding manifestations of SPD include mild mucous membrane bleeding, easy bruising, menorrhagia, and excessive bleeding following dental or general surgery. SPD may also occur as a component of the following syndromes:

- Hermansky–Pudlak syndrome: Features include delta SPD, oculocutaneous albinism, pulmonary fibrosis, and the accumulation of ceroid-like material in cells of the reticuloendothelial system. One subtype is due to a defective gene (called HSP1) on chromosome 10.

- Chediak–Higashi syndrome: Features include delta SPD with giant platelet granules, photophobia, nystagmus, pseudoalbinism, lymphadenopathy, splenomegaly, and increased susceptibility to infection. It is attributed to defects in a gene called CHS1 on chromosome 1, affecting protein trafficking.

- Thrombocytopenia with absent radius: Features include alpha SPD and absence of the radius bone.

- Wiskott–Aldrich syndrome: Features of this X-linked recessive disorder include delta SPD with other metabolic platelet defects, recurrent infections, eczema, lymphocytopenia, multiple cellular and humoral immunologic defects, and thrombocytopenia with microplatelets (small platelets); the thrombocytopenia may resolve following splenectomy. It is attributed to a genetic defect in a gene called WASP on the X chromosome, affecting signal transduction and other functions.

**Diagnosis**

See Table 11–16 for information on the laboratory evaluation for storage pool deficiency.

The bleeding tendency in uremia-induced hemorrhage is attributed to platelet dysfunction and endothelial cell dysfunction. Bleeding manifestations may be mild or severe and can include petechiae, ecchymoses, epistaxis, and purpura.

Hemostatic Defects in Uremia

Description

The bleeding tendency in uremia-induced hemorrhage is attributed to platelet dysfunction and endothelial cell dysfunction.

Bleeding manifestations may be mild or severe and can include petechiae, ecchymoses, epistaxis, and purpura. Paradoxically, chronic renal failure is also associated with an increased incidence of arterial and venous thrombosis, and, therefore, can influence hemostasis toward bleeding or clotting.

Diagnosis

See Table 11–17 for information on the laboratory evaluation for hemostatic defects in uremia.

Drug-induced Qualitative Platelet Dysfunction

Description

Platelet dysfunction may occur on ingestion of a wide variety of drugs, particularly aspirin and clopidogrel (Plavix). Due to the ubiquity of aspirin in over-the-counter medications, many medications are implicated in platelet dysfunction. Some patients consume multiple drugs, such as aspirin and clopidogrel, with different and additive antiplatelet effects and thereby inhibit platelet function by more than 1 mechanism. Drug-induced platelet dysfunction can present a high bleeding risk in patients with existing hemostatic defects, but typically does not result in clinically

significant bleeding in normal individuals. When hemorrhage does occur, there is usually an underlying hemostatic disorder affecting either the platelets or coagulation factors, or an anatomic lesion, such as an ulcer, that predisposes the patient to bleeding.

Commonly encountered coagulopathies that place patients at risk for bleeding when there is a superimposed drug-induced platelet defect include vWD, thrombocytopenia of any cause, and anticoagulation therapy. Hemorrhagic manifestations can include petechiae and purpura, ecchymoses, mucosal membrane bleeding, hematuria, epistaxis, and oozing from intravenous access sites and surgical incisions.

**Diagnosis**

Laboratory tests are of little value in predicting the clinical significance of drug-induced platelet defects. They can confirm the presence of abnormal platelet function, but cannot assess the risk of bleeding. Furthermore, laboratory abnormalities in platelet function are not specific for a particular drug. See Table 11–18 for information on the laboratory evaluation for drug-induced platelet defects.

**THROMBOTIC DISORDERS**

In this chapter, the disorders associated with thrombosis (Figure 11–5) are grouped into those with a relatively higher prevalence and those with a relatively lower prevalence. Among those with a higher prevalence is activated protein C resistance, which is produced by the Factor V Leiden mutation. This mutation is present in 3% to 5% of Caucasian populations. Other thrombotic disorders with a high prevalence are the prothrombin G20210A mutation, and the antiphospholipid antibody syndrome (an acquired disorder). The thrombotic disorders with a lower prevalence include protein C deficiency, protein S deficiency, and antithrombin deficiency. Elevated plasma homocysteine levels may also increase the risk for thrombosis. Plasminogen deficiency is also rare, and its association with thrombosis is controversial. Two other rare conditions, dys fibrinogenemia of certain types and essential thrombocythemia, can produce either thrombosis or bleeding. Also rare are TTP and HUS.

**Hypercoagulable States**

**Description**

Hypercoagulable states are associated with an increased risk for thrombosis (Table 11–19). There are both hereditary and acquired hypercoagulable states. Hereditary forms may arise from a quantitative or qualitative deficiency of a regulatory anticoagulant protein, such as protein C, protein S, or antithrombin (see Figures 11–2 and 11–3). Activated protein C resistance is caused by a mutation in the Factor V molecule (nearly always the Factor V Leiden mutation), which prevents activated protein C-mediated inactivation of Factor Va. The prothrombin G20210A mutation is prevalent in Caucasian populations, similar to Factor V Leiden. Prothrombin G20210A is a

</tr>
</tbody>
</table>

**Selected other acquired predisposing conditions for thrombosis**

For venous thromboembolism: postoperative state, immobility, trauma, obesity, congestive heart failure, pregnancy and postpartum state, estrogen and progesterone use, nephrotic syndrome, l-asparaginase therapy, infection, prolonged travel, dehydration, smoking, and malignancy

For arterial thromboembolism: atherosclerosis, damaged endothelium, bypass grafts, cardiac emboli (from atrial fibrillation, mitral stenosis, or mural thrombus following myocardial infarction), and arteritis

For both venous and arterial thromboembolism: disseminated intravascular coagulation, malignancy, myeloproliferative disorders, systemic lupus erythematosus, paroxysmal nocturnal hemoglobinuria, and heparin-induced thrombocytopenia

*If both protein C and protein S are decreased, vitamin K deficiency or warfarin intake should be considered, especially if the prothrombin time is prolonged; if protein C, protein S, and antithrombin are all decreased, decreased synthesis of these proteins from liver disease, or recent/active clotting with consumption of the factors, may be the explanation.
mutation in the promoter of the prothrombin gene, causing increased synthesis of prothrombin (Factor II). Hyperhomocysteinemia, a disorder in which there is an abnormally high level of plasma homocysteine, can be hereditary or acquired. Hyperhomocysteinemic individuals are at increased risk for coronary artery disease and deep venous thrombosis. However, studies have not yet shown that reducing slightly or moderately elevated homocysteine with vitamin therapy reduces the thrombotic risk. A block in the pathway at any 1 of the several steps results in the accumulation of homocysteine. When the homocysteine level is manyfold higher than the upper limit of normal, this very high value may contribute to the damaging effects on the blood vessel wall. Acquired hypercoagulable states arise from a diverse array of clinical conditions. They include malignancy, immobilization, surgery, trauma, obesity, smoking, infection, prolonged travel, and the use of oral contraceptives, estrogen replacement therapy, and progesterone, among many others. An acquired hypercoagulable state for which specific coagulation testing is available is the antiphospholipid antibody syndrome.

The presence of 1 hypercoagulable condition alone is not usually sufficient to initiate thrombosis. The presence of a second (or more), superimposed hypercoagulable condition (often called a “second hit”) appears to be required to provoke a thrombotic event. For example, a person with activated protein C resistance may not experience a thrombotic event until suffering major trauma as a “second hit.”

**Diagnosis**

Laboratory testing for hypercoagulable states is most often performed for patients presenting with a personal or family history of thrombosis. The laboratory evaluation for hereditary hypercoagulable states is best performed as a panel of test results. The most common disorders are activated protein C resistance (caused nearly always by Factor V Leiden) and prothrombin G20210A, and the less common are deficiencies of protein C, protein S, and antithrombin. Frequently, antiphospholipid antibody testing is performed in conjunction with the tests for hereditary hypercoagulable disorders. If all of these tests are negative and the clinical suspicion for a congenital hypercoagulable state remains high, additional testing for the more rare hypercoagulable disorders can be performed. There are many acquired conditions or treatments that reduce the level of protein C, protein S, and antithrombin in the test panel for hypercoagulability, but despite this, the risk for thrombosis is not significantly increased on that basis. For example, warfarin reduces the levels of protein C and protein S but reduces thrombotic risk. Antithrombin is lowered by heparin therapy. Pregnancy, oral contraceptives, and estrogen therapy can all decrease the activity of protein S, although they can induce a hypercoagulable state by other mechanisms. Active clot formation, liver dysfunction, or DIC can lower protein C, protein S, and antithrombin. In situations where such a confounding variable exists that alters the level of protein C, protein S, or antithrombin, the tests should be repeated (if possible) when the variable is no longer present to obtain the patient’s true baseline values. This should allow determination of whether a heritable deficiency of any of these 3 proteins truly exists:

- **Activated protein C resistance:** Usually, the first assay performed is a functional assay for activated protein C resistance. If the result is abnormal, genetic analysis is performed, to confirm whether Factor V Leiden is present in the heterozygous state, present in the homozygous state, or absent.
- **Prothrombin G20210A:** This mutation is identified by genetic analysis that can specifically identify heterozygous and homozygous states.
- **Hyperhomocysteinemia:** Plasma homocysteine levels are measured by a variety of automated methods.
- **Protein C, protein S, and antithrombin deficiencies:** Individual functional assays to measure the activity of these endogenous anticoagulant proteins detect both qualitative (normal number of abnormally functioning molecules) and quantitative (low number of normally functioning molecules) deficiencies. In contrast, an antigenic (immunologic) assay, which measures only the quantity of protein present, can detect quantitative but not qualitative deficiencies. Therefore, the first assay performed should be a functional assay. If the result is abnormal, an antigenic assay can be performed to determine if the cause of the decreased activity is a quantitative or qualitative deficiency of the protein.
LA (an antiphospholipid antibody): A variety of tests can be used to detect an LA. This antibody interferes with the cofactor action of phospholipid in the coagulation cascade in laboratory assays only (see the section “Antiphospholipid Antibodies: The Lupus Anticoagulant, Anticardiolipin Antibodies, and Beta-2 Glycoprotein I Antibodies” [Beta-2 GP I antibodies]). Various phospholipid-dependent coagulation test times, especially PTT-based or dilute Russell viper venom time (DRVVT) assays, can be used. The DRVVT is the clotting time obtained using Russell viper venom, which contains a Factor X activator.

- Anticardiolipin antibody or beta-2 GP I antibody (both are antiphospholipid antibodies): These antiphospholipid antibodies may or may not be associated with the presence of an LA (see the section “Antiphospholipid Antibodies: The Lupus Anticoagulant, Anticardiolipin Antibodies, and Beta-2 Glycoprotein I Antibodies”), and they are detected by enzyme-linked immunoassays.

See Table 11–19 for characteristics of the hypercoagulable states.

**Antiphospholipid Antibodies: The Lupus Anticoagulant, Anticardiolipin Antibodies, and Beta-2 Glycoprotein I Antibodies**

**Description**

Antiphospholipid antibodies recognize specific phospholipid–protein complexes rather than phospholipid alone. They can be immunoglobulin type IgG or IgM, or, less commonly, IgA. The LA is an immunoglobulin that can interfere with phospholipid-dependent coagulation reactions in laboratory assays without inhibiting the activity of any specific coagulation factor. It targets phospholipids bound to prothrombin, beta-2 GP I, protein C, protein S, or other proteins bound to phospholipids. Anticardiolipin antibodies are another type of antiphospholipid antibody, which target beta-2 GP I bound to a particular phospholipid, cardiolipin; these can be detected by anticardiolipin antibody immunoassays. Anti-beta-2 GP I antibodies also target beta-2 GP I.

An antiphospholipid antibody may occur in apparently healthy individuals with no detectable illness. It also occurs in patients with a variety of clinical conditions or disorders including:

- Systemic lupus erythematosus and other autoimmune disorders
- Malignancy
- Following ingestion of selected drugs (procainamide, quinidine, phenytoin, chlorpromazine, valproic acid, amoxicillin, augmentin, hydralazine, streptomycin, and propranolol have all been reported to induce an LA)
- Infectious diseases—bacterial (including spirochetal and mycobacterial), viral, fungal, and protozoal infections
- Following vaccination

Estimates of prevalence have been highly variable because results are completely dependent on the test(s) used for detection of antiphospholipid antibodies, and some methods are more sensitive than others. Approximately 2% of patients with a prolonged PTT will have an LA as the cause of the prolongation. LA is the most common cause of a prolonged PTT that remains prolonged in a PTT mixing study (a PTT performed on a sample of mixed patient and normal plasma). It is estimated that 1% to 5% of the general population has an antiphospholipid antibody. The frequency of antiphospholipid antibody in systemic lupus erythematosus patients is in the 30% to 40% range. Antiphospholipid antibodies due to infections are typically transient and asymptomatic.

Although the LA acts as an anticoagulant in vitro, it does not appear to be associated with hemorrhage, even with surgical challenge. Rare cases of bleeding in patients with the LA can almost always be attributed to specific abnormalities in hemostasis that happen to be present along with the LA. Decreased prothrombin (Factor II) is occasionally found with the LA. The LA can bind directly to prothrombin, but typically the LA does not neutralize the procoagulant activity of prothrombin even when it does bind to it. In an occasional patient, however, antibody binding does reduce the prothrombin concentration by accelerated clearance of prothrombin/antiprothrombin complexes, and these patients can have hemorrhagic complications. Concomitant thrombocytopenia is not infrequently found in patients with the LA, and this also may be a cause for hemorrhage.
Antiphospholipid antibodies are associated with an increased risk for venous and arterial thrombosis. The role of the antiphospholipid antibody in thrombosis is not clear, although several mechanisms for thrombosis have been proposed. The incidence of clinically apparent thromboembolism in patients with the LA, with or without systemic lupus erythematosus, is difficult to determine because of the variety of tests used to detect the LA. However, data suggest that the percentage of patients with the LA who will develop thrombosis is 1% per year if there is no history of thrombosis and 5.5% per year if there has been at least 1 prior thrombotic event. High titers of anticardiolipin or anti-beta-2-GP I antibodies present a higher risk for complications than low titers, and IgG is thought to be higher risk than IgM or IgA. There is a greater risk for thrombosis if more than 1 of the 3 antiphospholipid antibody tests (LA, anticardiolipin antibodies, and anti-beta-2-GP I antibodies) are abnormal.

Recurrent spontaneous abortion has been reported to be increased in patients with antiphospholipid antibodies. There is evidence suggesting that thrombosis and infarction in the placenta mediate antiphospholipid antibody-associated spontaneous abortion in a significant number of women experiencing recurrent fetal loss or premature birth.

Diagnosis

There are no “gold standard” tests that unequivocally establish the presence of antiphospholipid antibodies:

- **For the LA:** A prolonged PTT and a PTT mixing study that does not correct into the normal range are clues to the presence of the LA, although some PTT reagents are not sensitive to the LA. Therefore, it should be noted that the routine PTT is not an appropriate screening test for the LA. A PTT- or DRVVT-based test with a reduced amount of phospholipid can be used as a screening test for the LA. If it is prolonged, a 1:1 mixing study and a confirmatory assay should be performed. In the presence of an LA, the PTT or DRVVT usually remains prolonged when equal portions of patient plasma and normal plasma are mixed. Confirmatory assays demonstrate that the clotting time shortens toward normal when excess phospholipid is added, overcoming the LA effect. The PT is not typically increased by the LA, unless the patient has an associated hypoprothrombinemia or the thromboplastin used in the PT is one that is particularly sensitive to inhibition by the LA.

- **For anticardiolipin or anti-beta-2 GP I antibodies:** An enzyme-linked immunosorbent assay (ELISA) is used that quantitates IgG and IgM antibody levels in arbitrary units. IgA is also measured in some kits.

Patients with antiphospholipid antibodies may have a false-positive serologic test result for syphilis (such as Venereal Disease Research Laboratories [VDRL] and rapid plasma reagin [RPR]).

See Table 11–19 for information on the laboratory diagnosis of antiphospholipid antibodies.

**Thrombotic Thrombocytopenic Purpura**

**Description**

TTP is a clinical syndrome that is characterized by a triad (1-3 below, more commonly) or pentad (1-5 below, less commonly) of signs and symptoms:

1. Thrombocytopenia with generalized purpura, and mucous membrane bleeding
2. Hemolytic anemia (microangiopathic) sufficient to cause jaundice or pallor
3. Neurologic abnormalities, which may include fluctuating weakness, dysphagia, headache, dementia/behavioral changes, obtundation, seizures, diplopia, paresthesias, and coma
4. Fever
5. Renal dysfunction, which may include hematuria, proteinuria, or renal insufficiency

The characteristic, but not pathognomonic, pathology includes platelet and fibrin “hyaline” thrombi in the small arteries, arterioles, and capillaries in a widespread organ distribution. Organ ischemia and infarction that arise from these thrombi are thought to give rise to the observed fever and organ dysfunction. The etiology for TTP has been shown to be a deficiency of vWF-cleaving protease. Nonfamilial cases of TTP are a result of an inhibitor to the vWF-cleaving protease; the familial form of TTP is apparently caused by a constitutional deficiency of vWF-cleaving protease. Thrombotic thrombocytopenic purpura is a clinical syndrome that is characterized by a triad (more commonly) or pentad (less commonly) of signs and symptoms.
CHAPTER 11  Bleeding and Thrombotic Disorders

the protease. The unusually large forms of vWF in the plasma of patients with TTP promote the aggregation of platelets in vivo, which accounts for most of the clinical findings.

TTP can occur at any age but is most common between the ages of 20 and 50 years. Peak incidence is in the third decade. There is a female to male ratio of 3:2. TTP usually occurs as an acute, fulminant disease, but may also occur in a chronic form or in an acute relapsing form. The acute and acute relapsing types are often preceded by a viral prodrome. Nonspecific signs such as malaise, weakness, fatigue, and anorexia may predominate at first, until the above triad or pentad develops in days to weeks. The chronic type usually pursues an indolent, low-grade course, with ongoing disease activity for months.

Nonspecific manifestations in other organ systems resulting from ischemia may include:

- Cardiac: conduction defects, sudden death, and heart failure
- Pulmonary: lung infiltrates and acute respiratory failure
- Gastrointestinal: abdominal pain due to visceral ischemia, pancreatitis, and gastrointestinal mucosal hemorrhage

### Diagnosis

See Table 11–20 for information on the laboratory evaluation for TTP.

### Hemolytic–Uremic Syndrome

#### Description

HUS is a clinical syndrome with presentation and manifestations similar to TTP. Despite the clinical similarity, evidence has shown that the low levels of vWF-cleaving protease found in TTP are not found in HUS.

#### Hemolytic–Uremic Syndrome

BUN, blood urea nitrogen; PT, prothrombin time; PTT, partial thromboplastin time.
pronounced or absent in HUS; renal function is usually more impaired in HUS than in TTP; HUS occurs in a younger population than TTP with a peak incidence between 6 months and 4 years, with males and females equally affected; HUS is a more common entity than TTP; as with TTP, hyaline thrombi may be found, but in most cases they tend to be confined to the glomerular capillaries and afferent arterioles.

HUS occasionally occurs in adults, and is often distinguished from childhood HUS because of its strong association in adults with obstetrical complications such as eclampsia. The prognosis is worse in adults than in affected children, with an adult mortality as high as 60%.

Acute HUS occurs in nonfamilial and familial forms, which may have different causes. Nonfamilial forms are most often associated with a diarrheal illness caused by a Shiga-toxin-producing \textit{E. coli} (in particular, \textit{E. coli} O157:H7). Familial forms have been linked to abnormalities in complement factor H and factor I. The majority of childhood cases resolve without sequelae, if children with acute renal failure receive dialysis when necessary. The prognosis depends on the duration of renal failure and the severity of the neurologic disturbance. Renal function returns to normal in approximately 90% of childhood cases.

**Diagnosis**

See Table 11–21 for information on the laboratory evaluation for HUS.

**Anticoagulant Therapies**

Thrombosis can be treated and/or prevented with anticoagulant therapies, which are therapies that inhibit the coagulation cascade, thereby inhibiting fibrin clot formation. Since too little anticoagulation might allow new thrombosis to occur while too much anticoagulant can cause bleeding, laboratory tests can be used to determine how much anticoagulation is present in the patient, so that the dose can be adjusted if needed. For decades, heparin and warfarin were the only anticoagulants available for use. Heparin is given intravenously or subcutaneously, and warfarin is taken orally. As described previously, heparin inhibits multiple coagulation factors, and the effect of this inhibition is that heparin prolongs the PTT. Most PT reagents contain a heparin neutralizer that largely prevents significant PT prolongations for patients on heparin. Warfarin decreases the synthesis of active forms of Factors II, VII, IX, and X, which prolongs the PT. Different PT methods can demonstrate different degrees of prolongation with warfarin. Therefore, a formula is used to convert the PT into a more standardized number that takes into account the relative sensitivity of the PT reagent. This calculation is called the international normalized ratio (INR),

and it is meant to provide similar results no matter what method is in use by the laboratory. To be sure the correct amount of anticoagulation is present, heparin is closely monitored with the PTT, and warfarin is closely monitored with INR measurements.

Newer anticoagulants have emerged that do not routinely need monitoring with laboratory tests. Nevertheless, laboratory monitoring may still be occasionally indicated. Low-molecular-weight heparin, fondaparinux, rivaroxaban and apixaban inhibit Factor Xa. Therefore, these anticoagulants can be monitored with anti-Factor Xa assays. These are assays that can measure the concentration of the anticoagulant based on how much inhibition of Factor Xa is detected. Direct thrombin inhibitors (argatroban, bivalirudin, and dabigatran) inhibit thrombin, which prolongs the PTT and to a lesser extent the PT. A dilute thrombin time assay has been shown to have a linear relationship to therapeutic doses of dabigatran. The PTT can be useful to monitor argatroban. Bivalirudin is specifically approved for use during percutaneous coronary intervention (PCI), a cardiac catheterization procedure that requires anticoagulation that is monitored with a rapid, bedside whole blood clotting time test called the activated clotting time (ACT). If a patient has PCI with bivalirudin, the ACT is used.

Only warfarin, rivaroxaban, dabigatran and apixaban are administered orally. The other anticoagulants are administered parenterally.

See Table 11–22 for a summary of the mechanisms of action and the laboratory tests to measure the anticoagulation effect of these various anticoagulant therapies.

### Antiplatelet Therapies

Patients with arterial thrombosis, in particular myocardial infarction or ischemic stroke, are usually treated with antiplatelet therapy, to inhibit platelet activation. Unlike many anticoagulant therapies, laboratory testing is not yet routinely used to monitor antiplatelet therapy. Studies are ongoing to determine if laboratory monitoring of platelet therapy is beneficial. A variety of platelet-inhibiting medications are available. Aspirin reversibly inhibits cyclooxygenase in platelets, which prevents the generation of thromboxane A2 from arachidonic acid. This inhibits platelet aggregation because thromboxane A2 triggers the release of platelet granules and activates other platelets. Several GP IIb/IIIa inhibitors are available (abciximab, eptifibatide, or tirofiban). These agents inhibit platelet aggregation because GP IIb/IIIa on the platelet surface mediates platelet aggregation. Clopidogrel, prasugrel, and ticagrelor all inhibit an ADP receptor on the platelet surface, which ultimately inhibits activation of platelet GP IIb/IIIa. Dipyridamole inhibits platelets through multiple mechanisms.

---

A portion of this chapter, primarily the material in the section "Introduction to Hemostasis," was adapted with permission with modifications from Laposata M, Connor AM, Hicks, DG, Phillips DK. The Clinical Hemostasis Handbook. Chicago: Year Book Medical Publishers; 1989.

Transfusion medicine is the field of medicine that encompasses blood banking (the collection, preparation, testing, and storage of blood components and plasma derivatives) as well as the therapeutic uses of blood components, plasma derivatives, and apheresis technology. It also includes the collection, storage, and use of hematopoietic and other blood-derived cells. An overview of the steps from collection of the blood to transfusion of its components is shown in Figure 12–1. Briefly (with more complete descriptions to follow), blood is...
collected as whole blood or by apheresis from screened, volunteer donors, and samples of the blood are tested for infectious diseases and to determine the blood type. Whole blood may be fractionated into packed red blood cells (RBCs), platelets, and a plasma product. Alternatively, all 3 components can be collected by apheresis. Plasma can be further processed to provide albumin, clotting factor concentrates, and immunoglobulin preparations. The transfusion of blood components requires testing to be done to establish compatibility between the product and the intended recipient. Blood components may also be treated to reduce complications of transfusion (eg, remove leukocytes to prevent febrile reactions). As complex, biologically derived therapeutic agents, blood components and derivatives are responsible for a variety of potential untoward effects that must be evaluated and managed. The entire process, from blood collection to transfusion and posttransfusion evaluation, is described in this chapter (see Figure 12–1).

**COLLECTION OF BLOOD AND PREPARATION OF BLOOD COMPONENTS**

**Blood Collection**

The cornerstone of a safe blood supply is the volunteer blood donor who is motivated by altruism. In the past, the use of paid donors was associated with increased levels of transfusion-transmitted hepatitis. Concerns remain about the impact of significant financial incentives on the frank disclosure of health problems or high-risk behaviors that might disqualify a potential blood donor. In the United States, virtually all of the blood is collected from volunteer donors. Regional blood centers collect and distribute more than 90% of the US blood supply while hospital blood banks collect the remainder. The Food and Drug Administration (FDA) Center for Biologics Evaluation and Research regulates all aspects of blood collection and processing, but most blood banks and donor centers are also accredited, on a voluntary basis, by the American Association of Blood Banks (AABB). Blood donors are screened for behaviors or medical conditions that might make blood donation unsafe for them (eg, anemia, coronary artery insufficiency) or the donated blood hazardous for the transfusion recipient (eg, exposure to viral hepatitis, use of a teratogenic medication). The AABB has developed, and the FDA has sanctioned, a Uniform Donor Health Questionnaire that is in wide use in the United States and reflects the consistency of donor criteria throughout the country. To qualify for blood donation, the prospective donor must also pass a basic physical screening that includes temperature, blood pressure, pulse, and examination of the arms for signs of intravenous drug use, and have a hemoglobin level of at least 12.5 g/dL from a
finger-stick or venous blood sample. The collecting agency must check its records to be sure that the donor has not previously been disqualified from donating.

In the process of blood collection, the venipuncture site is disinfected and a needle, which is connected to a collecting set, is inserted into a vein in the arm. The collecting set includes a primary collection bag and several integrally connected satellite bags that are used to make components. The primary collection bag contains a solution that includes an anticoagulant (citrate) and a variety of substances, such as phosphate, adenine, and dextrose, which improve the recovery of the RBCs when transfused and permit their storage in the refrigerator for 35 to 42 days. The typical donation is approximately 450 to 500 mL of whole blood, but may not exceed 10.5 mL/kg, and must be collected in no more than 10 minutes if a unit of platelets is to be made. This volume of blood represents approximately 10% of the total blood volume of a donor weighing 70 kg, and its loss is well tolerated by healthy individuals. Samples of blood for serologic and infectious disease testing are also obtained at the time of donation, often by collecting the first 15 to 25 mL of blood drawn, which has the advantage of diverting blood most likely to be contaminated with skin bacteria away from the collection bag. Once the collection is complete, the needle is withdrawn from the donor's arm, and the tubing connecting the needle to the primary collection bag is heat-sealed off.

Component Preparation
Almost all of the whole blood collected is separated into its components—RBCs, platelets, and plasma—in order to be able to store each under optimal conditions. This separation process entails 2 centrifugation steps and relies on the system of integrally connected satellite bags to carry out all of the preparation steps in a closed, aseptic environment (see Table 12–1 for a description of blood components, and Chapter 2 for a diagram of blood component preparation). In the procedure used in the United States, RBCs are separated from platelet-rich plasma by the first, relatively low g force, centrifugation step. The platelet-rich plasma is expressed from the primary collection bag into one of the satellite bags that is heat-sealed off from the packed RBCs in the primary collection bag. The packed RBCs remaining in the primary collection bag may be stored for up to 35 days at 1°C to 6°C (CPDA-1 RBCs). In some collection systems, additional additive–preservative solution from another satellite bag may be added to the packed RBC, creating a product with a lower hematocrit (but identical RBC mass) and an additional week of storage (42 days).

The platelet-rich plasma, which was expressed off the packed RBC after the first spin, is then separated into platelets and plasma by a second, higher g force, centrifugation step. The platelet-poor plasma is expressed into another satellite bag after this second centrifugation step and is usually frozen within 8 hours of collection (as fresh frozen plasma [FFP]) or within 24 hours of collection (24-hour plasma). The platelet pellet that remains is suspended in 40 to 60 mL of plasma and is called a platelet concentrate or whole blood-derived platelets. The term “random donor platelets,” although commonly used, is inaccurate. Platelets are stored at 20°C to 24°C for up to 5 days, whereas the various plasma-derived components are stored frozen (≤−18°C for 1 year; ≤−65°C for 7 years). Since 1 transfusion dose for an adult patient consists of 4 to 10 units of platelet concentrates, it is common to use commercially available closed systems to pool and leukoreduce them.

FFP can be used to prepare another useful component, called cryoprecipitated antihemophilic factor (or “cryoprecipitate”). When FFP is thawed at 1°C to 6°C, a precipitate forms. Most of the plasma can be expressed into a satellite bag, leaving behind this cryoprecipitate that is suspended in 10 to 20 mL of plasma, refrozen, and then stored (≤−18°C for 1 year). Cryoprecipitate contains about half of the Factor VIII, von Willebrand factor, Factor XIII, and fibrinogen that was present in the original unit of plasma, but in a much smaller volume. The plasma remaining after the cryoprecipitate has been removed may also be refrozen. "Plasma–cryoprecipitate reduced" (or cryo-poor plasma) may be used as the starting material (source plasma) for the preparation of plasma derivatives such as albumin and immunoglobulins, and occasionally for replacement during plasmapheresis for patients with thrombotic thrombocytopenic purpura (see Table 12–2). Thus, each unit of whole blood can be separated into a unit of packed RBCs, a platelet concentrate, and either FFP or cryoprecipitate plus some other plasma product. The different plasma products (absent cryoprecipitate) may all be used as source plasma for the preparation of derivatives, such as albumin or immunoglobulin.

<tbody>
<tr>
<td>Packed RBCs</td>
<td>Packed RBCs are the product of a centrifugal separation of red cells from plasma; this component has a hematocrit of 55%-80%</td>
<td>Packed RBCs are used for treatment of a symptomatic anemia; this component may also be used for exchange transfusion when treating sickle cell crisis or hemolytic disease of the newborn</td>
<td>Packed RBCs provide RBC mass and increase oxygen-carrying capacity in the blood</td>
<td>RBCs must be ABO- and Rh-compatible, and crossmatched</td>
</tr>
<tr>
<td>RBCs, leukoreduced</td>
<td>Packed RBCs may be modified by removal of leukocytes by filtration or washing; washing RBCs is less effective at removing leukocytes than filtration techniques</td>
<td>The indications for this product are the same as for packed RBCs; leukoreduced RBCs are used for individuals who have experienced febrile reactions due to passenger WBCs in a blood component; they are also used to prevent alloimmunization in a patient who may require multiple platelet transfusions, or to prevent cytomegalovirus infection in a susceptible patient</td>
<td>Packed RBCs provide RBC mass and increase oxygen-carrying capacity in the blood</td>
<td>RBCs must be ABO- and Rh-compatible, and crossmatched</td>
</tr>
<tr>
<td>Fresh frozen plasma (FFP)</td>
<td>Plasma that is separated from the cellular components and frozen within 8 h of collection of whole blood is known as FFP</td>
<td>Because FFP contains significant levels of all the plasma coagulation factors, including Factors V and VIII that are labile, it is useful to control bleeding in patients who have multiple coagulation factor deficiencies; FFP should not be used to correct a deficit of blood volume; other volume expanders that are less potentially infectious should be used</td>
<td>FFP restores plasma proteins, particularly coagulation factors, and this may result in control of a bleeding episode</td>
<td>This component should be ABO-compatible with the recipient's RBCs, but crossmatching is not performed prior to transfusion; Rh type is not a consideration</td>
</tr>
<tr>
<td>Cryoprecipitate</td>
<td>Cryoprecipitate is generated by thawing FFP at 1°C-6°C; the precipitate is collected and refrozen; a typical bag of cryoprecipitate contains at least 80 units of Factor VIII and at least 150 mg of fibrinogen in a volume of less than 25 mL</td>
<td>This component is used for patients with a deficiency of fibrinogen (often from disseminated intravascular coagulation), or deficiency of Factor XIII</td>
<td>Transfusion of cryoprecipitate to raise fibrinogen levels to greater than 100 mg/dL may be useful to provide hemostasis for fibrinogen deficiency</td>
<td>Crossmatch testing is unnecessary; although ABO-compatible cryoprecipitate is preferred, it is not necessary; the Rh type is not a consideration</td>
</tr>
<tr>
<td>Platelets collected by apheresis</td>
<td>Platelets obtained by apheresis contain at least $3 \times 10^{11}$ platelets/unit; the product has a volume between 200 and 400 mL</td>
<td>Platelet transfusions are indicated for patients who are thrombocytopenic due to decreased platelet production or blood loss and for those patients who do not have an adequate number of functioning platelets; platelet transfusions are not usually effective in conditions associated with rapid platelet destruction; platelets may be useful in preventing a bleeding episode if given as a prophylactic measure to patients with very low platelet counts</td>
<td>The elevation of the platelet count in a thrombocytopenic patient or the transfusion of functionally active platelets into a patient with dysfunctional platelets can result in the cessation or prevention of bleeding</td>
<td>Although crossmatching is not necessary, platelet products that are ABO-compatible with the recipient are preferred to minimize the infusion of incompatible plasma</td>
</tr>
</tbody>
</table>

Continued next page—
Platelet concentrates (whole blood-derived platelets)  
Platelet concentrates are obtained from a single unit of whole blood, and contain at least $5.5 \times 10^{10}$ platelets; suspended in 40-60 mL of plasma, which is stored at 20°C-24°C.

Granulocytes collected by apheresis  
Granulocytes are collected from a single donor by apheresis; the product, which contains other blood cells as well, is in a volume of 200-300 mL.  
Granulocytes may be indicated for the patient who has both neutropenia and a documented infection that is not responsive to therapy; this product should not be used for prophylaxis against infection; in general, it has been more effective in infants than in adults.

Crossmatching must be performed before transfusion because of the large number of RBCs in the product; in addition, the granulocytes are very labile, so this product should be transfused as soon as possible after collection.

**TABLE 12–2 Derivatives of Blood Components and Indications for Their Use**

<table>
<thead>
<tr>
<th>Derivative</th>
<th>Description and Indication</th>
</tr>
</thead>
<tbody>
<tr>
<td>Factor VIII</td>
<td>Prepared for treatment of hemophilia A; Factor VIII can be purified from human plasma and treated to remove and inactivate infectious agents; recombinant Factor VIII products are available and commonly used; some plasma-derived preparations contain significant amounts of von Willebrand factor and are suitable for treatment of this disease as well.</td>
</tr>
<tr>
<td>Factor IX</td>
<td>Prepared using methods similar to those for Factor VIII; it is used for the treatment of patients with hemophilia B; recombinant factor IX is available and commonly used; concentrates that contain Factors II, VII, and X along with Factor IX are also available, and are known as prothrombin complex concentrates; some of these concentrates are potentially thrombogenic and are therefore not the preferred product for treatment of hemophilia B.</td>
</tr>
<tr>
<td>Albumin</td>
<td>Prepared from pooled donor plasma as a 5% or a 25% solution in a manner that removes infectious agents; albumin is used as replacement fluid for plasmapheresis, for hypoalbuminemic patients with acute lung injury, in conjunction with large-volume paracentesis, for diuresis in patients with ascites unresponsive to diuretics, in selected patients with subarachnoid hemorrhage to prevent vasospasm, and in selected burn patients; it should not be used routinely for volume expansion when crystalloid or synthetic colloid volume expanders such as dextran and hydroxyethyl starch are available.</td>
</tr>
<tr>
<td>Intravenous immunoglobulin (IV Ig)</td>
<td>The IgG fraction prepared from pooled donor plasma is processed to minimize IgG dimerization and remove or inactivate infectious agents; used as antibody replacement therapy in humoral immunodeficiency states (see Chapter 3) and in the treatment of selected autoimmune disorders such as idiopathic or immune thrombocytopenic purpura (ITP).</td>
</tr>
<tr>
<td>Rh immune globulin</td>
<td>The IgG fraction prepared from pooled plasma from donors with high-titer anti-D treated to remove or inactivate infectious agents; administered by intramuscular injection to Rh-negative women to prevent their alloimmunization by the Rh-positive RBCs of their offspring; Rh-negative women should receive this product at 28 weeks of gestation and again within 72 h of the birth of an Rh-positive baby, or at the time of abortion, miscarriage, vaginal hemorrhage, ectopic pregnancy, abdominal trauma, or invasive procedure such as amniocentesis or chorionic villus sampling; an intravenous formulation of this product is used for treatment of ITP.</td>
</tr>
<tr>
<td>Antithrombin concentrate</td>
<td>Prepared for treatment of patients with low amounts of circulating antithrombin who are susceptible to thrombosis; antithrombin is purified from pooled human plasma and treated to remove or inactivate infectious agents.</td>
</tr>
<tr>
<td>Recombinant, activated Factor VII</td>
<td>A recombinant version of activated Factor VII prepared for treatment of patients with acquired Factor VIII and Factor IX inhibitors and for patients with congenital Factor VII deficiency; widespread off-label use in bleeding patients with complex coagulopathies is being tempered by poor outcomes in randomized trials; should be used with caution in patients with prothrombotic tendencies.</td>
</tr>
</tbody>
</table>
Blood components also may be donated by a procedure known as apheresis, in which whole blood is removed from the donor, the component of interest (plasma or platelets most commonly, but RBCs as well) is removed, and the remaining blood elements are returned to the donor (see Chapter 2 for a diagram of apheresis). This procedure may be done manually, but is now usually carried out using an automated device. Using an apheresis instrument, whole blood is drawn from the donor's vein as an anticoagulant solution (usually citrate) is added, and pumped into a centrifuge where it is separated into its components. The component of interest is drawn into a collection bag, and the rest of the blood is returned to the donor via the same or a different vein. This process may be discontinuous (filling the instrument, separating the components, returning the residual blood, and repeating the cycle) or continuous (using separate lines to draw blood into the instruments and return it to the donor). The entire extracorporeal circuit is sealed except at the points of contact with the donor's vein(s). Apheresis is commonly used to obtain plasma, usually for further processing into derivatives such as albumin, clotting factor concentrates, and immunoglobulins, as well as to obtain platelets. A unit of apheresis platelets (commonly called "single donor platelets") contains more platelets than a unit derived from a whole blood donation. Transfusion of a unit of apheresis platelets, which must contain at least $3 \times 10^{11}$ platelets, usually elevates an adult patient's platelet count by 30,000 to 50,000 platelets/$\mu$L. Since 1 unit of whole blood-derived platelets must only contain $5.5 \times 10^{10}$ platelets, the usual adult dose is 4 to 10 units or 1 unit/10 kg. Whole blood-derived platelets are less expensive to prepare than apheresis platelets because they do not require special equipment for their isolation. However, apheresis platelets can easily be prepared in such a way that they contain very few residual white blood cells ("process leukoreduced"), which is an advantage for some patient groups.

Granulocytes also can be harvested by apheresis for transfusion to patients who are neutropenic and suffering from severe infection. Instruments designed to collect RBCs by apheresis (typically 2 units at a time if the donor meets the somewhat more stringent size and hematocrit requirements) or various combinations of RBCs, platelets, and plasma are also in use. Finally, apheresis is used to collect peripherally circulating hematopoietic progenitor cells (HPCs) for autologous and allogeneic HPC transplantation.

Testing of Donated Blood

Donated blood is held in quarantine following collection while a variety of laboratory tests are performed using blood specimens obtained from the donor. The ABO and Rh types are determined on an RBC sample obtained at each donation, and the donor serum or plasma is screened for the presence of unexpected RBC alloantibodies. The concern is that such alloantibodies could cause destruction of a transfusion recipient's RBCs if they express the target antigen. Plasma or platelets from a donor with an alloantibody are not used for transfusion, although RBCs are generally safe, particularly if they have been saline washed. Records from any previous donations, including the results of ABO and Rh typing, are also checked, to reduce the opportunity for donor or unit misidentification.

Infectious Disease Testing

Transmission of viruses, bacteria, and parasites by transfusion of blood components has been well documented. To minimize infectious disease transmission, blood donors are screened for evidence of infection and for participation in activities that may have exposed them to infectious agents. In addition, each blood donation is subjected to several tests for infectious agents before it is made available for transfusion. The tests required for each donation are shown in Table 12–3. Platelets, which are stored at 20°C to 24°C, must also be screened for evidence of bacterial contamination, which is currently responsible for the majority of transfusion-transmitted infections. Several commercial systems have been licensed for the testing of leukoreduced apheresis and whole blood-derived platelets. All donors must be screened once for antibody to Trypanosoma cruzi, the organism that causes Chagas disease, and deferred indefinitely if they are positive. Thereafter, donors do not need to be retested unless they have a possible exposure, that is, residence in an endemic area of South or Central America.

* Determined locally and may vary by season and/or for detection of WNV-infected mosquitoes by public health surveillance.

* Testing is done once on all donors and is only repeated if there is another exposure, that is, residence in an endemic area of South or Central America.

### COMPATIBILITY TESTING

#### Pretransfusion Testing to Assess Donor/Recipient Compatibility for Blood Components Containing RBCs

Prior to transfusion, the compatibility of donor RBCs with the intended transfusion recipient must be established (see Tables 12–4 and 12–5 for RBC compatibility issues). Part of this process involves various serologic tests. However, an equally important part of this process is the proper identification of the patient when the blood bank specimen is obtained, and again when the transfusion is initiated. Misidentification of patients and mislabeling of specimens are the most common serious errors encountered in transfusion. ABO mistransfusion as a result of this kind of error is far more frequent than the transmission of HIV and all of the hepatitis viruses, combined. Compatibility testing includes:

- The identification of patient and proper labeling of the specimen for compatibility testing. The blood bank specimen (tube of blood) must be labeled at the bedside using the patient’s armband for identification. The label must include 2 patient identifiers (typically name and medical record number) and the date. There must also be some means of identifying the phlebotomist (commonly, but not necessarily, by signing or initialing the tube or requisition).

Misidentification of patients and mislabeling of specimens are the most common serious errors encountered in transfusion. ABO mistransfusion as a result of this kind of error is far more frequent than the transmission of HIV and all of the hepatitis viruses, combined.
• The determination of the ABO and Rh type of the donor. The collecting facility determines the ABO group (by front- and back-typing as described below) and Rh type of the donated unit (and checks prior records). The hospital transfusion service must confirm the ABO group (front type only) and the Rh type of Rh(D)-negative units that have been received from the collecting facility.

• The determination of the ABO and Rh type of the patient on a current specimen, and a comparison to previous records, if any. The ABO group (front and back types) and Rh type are determined on a current specimen. The specimen must be <3 days old for any patient who has been transfused or pregnant within the last 3 months; however, many transfusion services require new specimens every 3 days to keep things simple.

• A screen of the recipient’s serum/plasma for unexpected RBC alloantibodies. If unexpected antibodies (ie, not anti-A or anti-B) are found, as described below, the antigen specificity of these antibodies must be identified to establish the risk of a hemolytic transfusion reaction (HTR) and to help identify potentially compatible donor RBCs that lack the target antigen. A record check for previously identified alloantibodies must also be made.

• The performance of a crossmatch (see Chapter 2 for illustration of the crossmatch). Several techniques for performing the crossmatch are described below.

• The identification of the patient when the transfusion is initiated. The patient must once again be properly identified using the armband to be sure that the unit is intended for the patient. The armband is the only link between the patient, the specimen, and the blood component.

**ABO Grouping**

After the identification of the patient and the specimen for compatibility testing, the most important step in assuring the safety of an RBC transfusion is the determination of the ABO group of the donor unit and the intended recipient. The specificity of the A and B blood group antigens lies in the presence of carbohydrate structures that are borne by membrane-associated glycoproteins and glycolipids. The A gene encodes a glycosyltransferase that attaches an N-acetylgalactosamine residue to the core structure (called “H”) while the B gene encodes an enzyme that transfers a galactose residue. These 2 different residues impart A or B serologic activity, respectively, to the glycoprotein or glycolipid core structure. The O gene, which is a phenotypic recessive, does not encode for an active enzyme, so the RBC of people who are group O are coated with an unmodified H structure. Since the A and B genes are codominant, people who inherit 1 copy of each will have both enzymes, and thus both A and B antigens will be expressed on their RBCs.

During the first year of life, individuals begin to make antibodies to whichever A and B antigens they lack. Thus, a person with A antigen on his or her RBCs (group A) has naturally occurring anti-B antibodies in the plasma (see Table 12–4). It is the presence of these antibodies (called isoagglutinins because of their ability to agglutinate RBCs in vitro) that makes ABO mis-transfusion so hazardous. The isoagglutinins are largely IgM and fix complement readily. Hence, they can cause intravascular hemolysis.

Because determining the ABO group is so critical, it is required not only to test for A and B antigens on the RBCs but also to demonstrate the presence of the appropriate anti-A and anti-B isoagglutinins in the plasma or serum (see Chapter 2 for a diagram of ABO and Rh typing).
The presence of A or B antigens on patient or donor RBCs is detected by combining them with reagent "anti-A" in 1 test tube and reagent "anti-B" in another test tube, and then assessing RBC agglutination. Agglutination with anti-A, for example, indicates the presence of A antigen on the RBCs. This test is called the "front" or "cell" typing. The plasma of a patient or donor is tested for the presence of anti-A or anti-B antibodies by combining the plasma with reagent RBCs known to be either group A or group B, and then assessing RBC agglutination. Agglutination of the reagent B cells indicates the presence of anti-B isoagglutinin in the plasma, which would be the expected finding in a person who is blood group A. This test is called the "back" or "serum" typing. The results of the front- and back-typing must be congruent.

Rh Typing

The second most important antigen system with respect to transfusion safety is the Rh system. Approximately 85% of Caucasians express the D (or Rh) antigen and are called D (or Rh)-positive (see Table 12–4). Rh-negative individuals, who lack the D antigen, are vulnerable to development of an alloantibody to the D antigen, the most immunogenic antigen on human RBCs, if they are exposed to D-positive RBCs by transfusion or, for a woman, by maternal–fetal hemorrhage. Anti-D is the most common cause of severe hemolytic disease of the newborn, although the frequency of this complication of pregnancy has been considerably decreased since the advent of Rh immune globulin. This product is an immunoglobulin fraction obtained by pooling the plasma of people with high-titer anti-D. When given by intramuscular injection to individuals who have been exposed to D-positive RBCs (eg, women pregnant with a D-positive fetus), it reduces the chance of sensitization presumably by binding to D-positive fetal cells, leading to their rapid clearance from the maternal circulation before an immune response can be generated (see the section "Hemolytic Disease of the Newborn [HDN]" in Chapter 10).

The Rh type is determined by incubating the RBCs with a reagent antibody to the D antigen. Rh-positive cells expressing the D antigen are agglutinated by the reagent antibody. RBCs that do not agglutinate in the presence of the Rh antibody are incubated a second time, usually after the addition of an enhancer of agglutination. RBCs that do not agglutinate after this second step are considered to be Rh(D)-negative. A small number of people have RBCs that do not agglutinate in the first step but are agglutinated after the second, enhanced, incubation step. These individuals are considered to have the weak D (formerly D*) phenotype. Donors, and usually patients as well, who are weak D are treated as if they are D-positive, since some weak D RBCs can elicit the formation of anti-D alloantibodies in D-negative individuals, or can be the target for anti-D alloantibodies.

The RHD gene is located on chromosome 1 immediately adjacent to the highly homologous RHCE gene, and the 2 are inherited as a haplotype exhibiting linkage disequilibrium. The RHD gene encodes for the D protein that expresses D ("Rh") antigenic activity. The most common mechanism for the Rh(D)-negative phenotype (especially among people of Caucasian background) is the complete absence of the RHD gene. This phenotype is often represented as "d," but in fact there is no "d" gene or "d" protein. These individuals lack the D protein altogether. The RHCE encodes for a protein that is structurally very similar to the D protein, but carries 2 different antigens, each of which has 2 common, codominant alleles: C/c and E/e. Since these genes are inherited as a haplotype, a shorthand nomenclature is in wide use and is shown in Table 12–5.

The Antibody Screen and the Indirect Antiglobulin Assay Used to Detect Antibodies

To determine if the patient has an alloantibody to a RBC antigen, an antibody screen is performed. In this test, the patient's serum or plasma is combined with 2 or 3 reagent RBCs that are specifically chosen because they bear a number of the antigens to which clinically significant RBC alloantibodies are made. These cells are group O so that they will not be agglutinated by the anti-A or anti-B isoagglutinins that may be present. If the patient serum does not produce agglutination of the reagent screening cells, then no unexpected RBC alloantibodies are present.

Although the anti-A and anti-B isoagglutinins are predominantly IgM and readily produce agglutination in vitro, most of the other clinically significant RBC alloantibodies are IgG and do not. To detect IgG alloantibodies, an assay called the indirect antiglobulin test (formerly the
indirect Coombs test) is used in the antibody screen (see Chapter 2 for a diagram of the indirect antiglobulin test). In this technique, the patient’s serum is combined with the reagent screening cells, often in the presence of an additive, such as low ionic strength saline or polyethylene glycol, which promotes binding of antibody to RBCs, and the mixture is incubated at 37°C. If an RBC alloantibody is present, it will bind to the screening cell with the target antigen. The cells are then washed with saline, and the “antiglobulin reagent” is added. Antiglobulin reagent consists of a mixture of antibodies to IgG and/or complement. These antibodies bind to any IgG or complement attached to the screening cell. By binding to IgG or complement on adjacent target cells, the anti-IgG “crosslinks” the RBCs and produces RBC agglutination in vitro. It is called the indirect antiglobulin test because it requires first an incubation with the alloantibody (the serum sample) followed by a second step when the antiglobulin reagent is added. The antiglobulin test is commonly performed in a test tube, but has also been adapted to assays based on solid phase or gel column techniques.

If 1 or more of the screening cells is agglutinated by the patient’s serum, indicating the presence of an RBC alloantibody, steps must be taken to identify its specificity by determining its target antigen. This is accomplished again using the indirect antiglobulin test and adding the patient’s serum to a panel of group O RBCs (typically around 10) that have been chosen to express the target antigens of the most commonly encountered clinically significant alloantibodies. The pattern of which panel cells are agglutinated in the indirect antiglobulin test can be used to determine the antigen to which the patient’s alloantibody is directed. Based on the accumulated clinical experience with alloantibodies of a given specificity, it is usually possible to predict the likelihood that a particular alloantibody will cause a hemolytic transfusion reaction (HTR) or hemolytic disease of the newborn (see Table 12–6). If the alloantibody has the potential of

causing hemolysis, donor RBCs that lack the target antigen must be chosen for transfusion. The typing of RBCs for specific antigens is accomplished in a manner similar to that used for the determination of the ABO and Rh type using commercial antisera directed at specific antigens. Patients who have multiple alloantibodies, or alloantibodies directed at high-frequency antigens, may pose the challenge that very few donors will lack the target antigen(s). Under these circumstances, the blood bank may have to screen the red cell inventory for antigen-negative units, request their blood supplier to do the same, or, in some instances, locate suitable units through a national rare blood registry.

The RBC Crossmatch

There are 3 crossmatch techniques in common use: the antiglobulin technique crossmatch, the immediate spin crossmatch, and the electronic crossmatch.

The antiglobulin crossmatch was the standard for years and still must be performed when a patient has an RBC alloantibody or even a history of having had one (see Chapter 2 for a diagram of the blood crossmatch). This crossmatch procedure is very similar to the antibody screen and is based on the indirect antiglobulin technique, except in this case the patient's serum is combined with RBCs from the donor unit. If the patient has an alloantibody to the donor RBCs, the antibody will become bound to the donor RBCs during the incubation step, and the cells will be agglutinated by the antiglobulin reagent added in the final step. If agglutination occurs, the crossmatch is incompatible and the unit of RBCs should not be transfused to that patient. If the RBCs from this donor were mistakenly transfused, they would be destroyed prematurely, that is, an HTR would occur. If there is no agglutination, the patient does not have alloantibodies to the antigens present on this donor's RBCs, and the crossmatch is compatible.

The immediate spin crossmatch is done by combining the patient's serum with a sample of the donor RBCs intended for transfusion, centrifuging them without incubation or the use of the antiglobulin reagent, and observing them immediately for agglutination. This technique detects ABO incompatibilities, but is not sensitive to the presence of other RBC alloantibodies. It may only be used in patients who do not have unexpected alloantibodies (ie, they have a negative antibody screen), in massive transfusion (transfusion of the equivalent of 1 entire blood volume), and in emergency circumstances when an abbreviated crossmatch procedure is imperative for providing blood rapidly.

In the electronic crossmatch, blood bank personnel rely on the computer to verify the ABO (and Rh) compatibility between donor RBCs and the patient. A number of requirements must be met by the information system and the bench procedures involved in the typing, and extensive validation must be performed. This technique is again only suitable for patients who do not have unexpected RBC alloantibodies, or in emergency situations.

Direct Antiglobulin Test (Formerly Direct Coombs Test)

This test detects the presence of IgG or complement that is bound, in vivo, to the patient's RBCs, by using antiglobulin reagent specific for IgG or various complement components including C3b, C3d, and/or C4d. In this technique, the patient's RBCs are washed with saline, and the antiglobulin reagent is then added directly (hence the name of the test) (see Chapter 2 for a diagram of the direct antiglobulin test). The cells are observed for agglutination after incubation. The presence of RBC coated with immunoglobulin and/or complement is evidence of immune-mediated hemolysis. Disorders associated with a positive direct antiglobulin test include hemolytic disease of the newborn, autoimmune hemolytic anemia, and drug-induced hemolytic anemia. A positive direct antiglobulin test result is also observed in patients experiencing an HTR where donor RBCs are circulating coated with the recipient's alloantibody. Note that most patients with positive direct antiglobulin tests do not have hemolysis. A positive direct antiglobulin test is found in many patients with lymphoproliferative and autoimmune disorders, or who are taking various medications such as procainamide, vancomycin, and drugs in the penicillin and cephalosporin families.

If a patient has an RBC autoantibody, especially if it is an IgG, it may interfere with routine serologic testing, especially any test that is based on the indirect antiglobulin technique such as the antibody screen and the crossmatch. Absorption techniques are used to remove the autoantibody from the patient's plasma, but leave any alloantibody behind. In the autologous absorption
technique, the patient’s RBCs (after treatment to remove any autoantibody) are incubated with
the patient’s plasma. The autoantibodies bind to the patient’s RBC, but any alloantibodies present
do not since the patient lacks those antigens, by definition. After absorbing out all of the autoan-
tibody (which may take a few cycles with fresh batches of the patient’s RBCs) the autoabsorbed
plasma can be tested for alloantibodies using the conventional antibody screen described above.
If the patient has been recently transfused, however, this absorption technique cannot be used,
because the transfused cells might absorb some of the alloantibody as well as the autoantibody
if they happen to bear the target antigen. In this case the RBCs used for the absorption may be
phenotypically matched to the patient, or several cells may be chosen, each of which displays a
different array of RBC antigens—hence the name, the heterologous absorption technique. The
sample of patient plasma that was absorbed by the heterologous cells is then also tested for RBC
alloantibodies using the conventional antibody screen described above.

**Compatibility Testing for Other Blood Components**

**That Do Not Contain RBCs**

Compatibility testing for blood components without RBCs (ie, platelets and plasma) is much less
complex than it is for products with RBCs since no crossmatching must be done. ABO grouping
of donor units and the patient must be performed to avoid the transfusion of plasma that is ABO-
incompatible with the recipient’s RBCs. The amount of anti-A and/or anti-B isoagglutinin in a
unit of apheresis platelets or FFP (200-300 mL) could lead to destruction of some of the recipi-
ent’s RBCs if there were an ABO mismatch. Rh-negative recipients may receive plasma products
or apheresis platelets from a donor of any Rh type, since these components do not contain RBCs.
Whole blood-derived platelets from Rh-negative donors may be preferentially selected for Rh-
negative patients, particularly if there is visible RBC contamination of the platelet product, to
avoid the possibility of alloimmunization to the D antigen.

**Molecular Techniques in Immunohematology**

In the last 20 years, molecular techniques have greatly increased our understanding of blood group
antigen structures and their genetics, and have explained many of the serologic conundrums that
baffled blood bankers for decades. Although not in routine use in the hospital transfusion service
at this point, a widening array of applications has been making its way into the clinical arena.
Some of these applications include:

1. **Genotyping blood donors**—Microarray-based platforms and mass spectrometry techniques
   have been used to genotype large numbers of blood donors for a number of the most
   common clinically significant antigens. The availability of this information facilitates the
   identification of donor units for patients who require RBC with a specific phenotype.
2. **Genotyping patients**—Similar technology can be applied to individual patients in
   circumstances when it is difficult to obtain a reliable phenotype by serologic methods, for
   example, in patients who have already been transfused or who have autoantibodies.
3. **Hemolytic disease of the newborn**—Detection of the \( RHD \) gene in the fetus of an
   alloimmunized mother can be performed using amniotic fluid or maternal plasma, thereby
   establishing whether or not the fetus is at risk for hemolytic disease of the newborn. The
   absence of the \( RHD \) gene in the fetus also obviates the need for additional, more invasive
   testing of the fetus, such as per-umbilical blood sampling. It is also possible to determine
   whether or not the father is homozygous for the \( RHD \) gene.
4. **Genotyping in the absence of serologic reagents**—Typing sera for some clinically
   significant blood group systems, such as Scianna and Dombrock, are not routinely
   available, and others are periodically in short supply. Genotyping has been used as an
   alternative in these situations.

Other potential applications:

1. **Extended electronic crossmatching**—The use of the electronic crossmatch to insure
   ABO and RhD compatibility between donor RBC and recipient is well established.
   The extension of this technique for matching for other clinically significant antigens
would be feasible if more extended genotype information was available for donors. This approach could be used in 2 circumstances:

a. Alloimmunized patients—for example, the database could be searched for donor RBCs that were A, R1r, Kell (K1) negative for a patient who was group A with anti-E and anti-K. Only these units would require antigen confirmation (serologically according to current regulations) and crossmatching.

b. Multiply transfused patients—Prospective genotype matching could be performed for transfusion-dependent patients, such as those with sickle cell disease, thalassemia, or aplastic anemia, to reduce the incidence of alloimmunization and delayed HTRs, especially the hyperhemolysis syndrome.

2. Autoimmune hemolytic anemia—The evaluation of patients with autoimmune hemolytic anemia is time-consuming and technically demanding, especially if they require autologous or heterologous absorptions. The goal of identifying units suitable for transfusion could be met, and perhaps more rapidly, by extended genotype matching.

### INDICATIONS FOR TRANSFUSION

Table 12–7 is a list of indications for transfusion of RBCs, platelets, plasma, and cryoprecipitate.

#### Red Blood Cells

A National Institutes of Health (NIH) Consensus Conference established broad parameters for perioperative RBC transfusion. Although the conclusion of the conference was that “no single measure can replace good clinical judgment as the basis for decisions regarding perioperative transfusion,” it was suggested that patients with hemoglobin levels exceeding 10 g/dL (100 g/L) rarely require transfusion, while those with hemoglobin levels less than 7 g/dL (70 g/L) frequently do.

Hgb, hemoglobin; INR, international normalized ratio.
rarely require transfusion, while those with hemoglobin levels less than 7 g/dL (70 g/L) frequently do. Several professional organizations have also established guidelines for RBC transfusion. There have been a small number of randomized trials comparing the clinical outcomes of liberal and stringent RBC transfusion triggers that have consistently failed to demonstrate any benefit of transfusing patients for hematocrits of 30% (10 g/dL) compared with triggers as low as 21% (7 g/dL).

**Platelets**

Indications for platelet transfusion have also been addressed by an NIH Consensus Conference and by professional organizations. Of particular interest in the last several years has been a reassessment of the use of prophylactic platelet transfusions in thrombocytopenic patients with marrow failure. In general, the traditional trigger level of 20,000 platelets/μL for prophylactic transfusion has been replaced with a level of 10,000 platelets/μL. There has even been a challenge to the utility of any prophylactic platelet transfusion, including before minor procedures such as line placement and lumbar puncture. This challenge suggests that platelets should only be administered in cases of actual bleeding. Appropriate uses of platelets in other settings are included in Table 12–7.

**Fresh Frozen Plasma**

Clinical situations in which FFP is likely to be useful also have been established by an NIH Consensus Conference and professional organizations. FFP has been used as replacement therapy for deficiencies of clotting factors and regulatory proteins, including protein C and protein S, for which specific concentrates or recombinant products are not available. The use of FFP to reverse mild coagulation abnormalities is probably not warranted. The risk of bleeding appears to be very low when the prothrombin time (PT) and the international normalized ratio (INR) derived from it are only mildly elevated (PT is <1.5 times the control or the INR is ≤1.5). The same can be said for mild elevations of the partial thromboplastin time (PTT) associated with coagulation factor deficiencies. It is also unlikely to provide any benefit to patients with mild elevations in the PT or PTT who are undergoing minor procedures (eg, line placement). On the other hand, FFP is effective in the treatment of thrombotic thrombocytopenic purpura, reversing the effects of warfarin in an emergency situation, the treatment of the bleeding patient with disseminated intravascular coagulation, and massive transfusion cases.

**Cryoprecipitate**

The practice of using cryoprecipitate as a source of fibrinogen and Factor XIII is well accepted. In addition, cryoprecipitate can be mixed with thrombin to form topical fibrin "glue," which is used to initiate anatomic connections and control bleeding over large surfaces; however, products with standardized amounts of fibrinogen that have undergone viral inactivation procedures are now commercially available and are generally preferable. The role of cryoprecipitate in the treatment of bleeding in uremic patients is controversial. Cryoprecipitate is no longer recommended for treatment of hemophilia A or von Willebrand disease because of the availability of other products.

**COMPLICATIONS OF BLOOD TRANSFUSION**

An adverse effect of blood transfusion occurs in approximately 3% of transfusions in the United States. These complications of transfusion can be classified as immunologic, infectious, or due to the chemical or physical characteristics of blood components.

**Immunologic Reactions**

**RBC Reactions**

**Hemolytic Transfusion Reactions**

Although HTRs are much discussed, they are fortunately quite uncommon, reflecting the efficacy of the serologic and procedural techniques in place to prevent their occurrence. Although HTRs occur with less than 0.1% of the units transfused in the United States, they can be life-threatening. It bears noting that fatal, acute HTR due to ABO incompatibility is a more frequent adverse
outcome of transfusion than infection with HIV or HCV, and it is more often the result of patient or sample misidentification than to serologic mishaps or exotic blood types.

HTRs are mediated by antibodies directed against alloantigens present on transfused RBCs. Most alloantibodies to RBC antigens, other than the AB isoagglutinins, develop in response to exposure to allogeneic RBCs by transfusion or maternal–fetal hemorrhage. There are hundreds of RBC antigens comprising more than 50 systems. Fortunately, only a small proportion of these have clinical significance. In addition to the AB isoagglutinins, antibodies to antigens in the Rh, Kell, Duffy, Kidd, and MNSs systems are responsible for the preponderance of HTRs. Identification of these alloantibodies, by the techniques discussed above, is important because the degree and severity of hemolysis differs among them.

HTRs can be either acute, occurring within 24 hours of transfusion, or delayed, in a reaction that appears 5 to 7 days (range 3-21 days) after the transfusion. Acute reactions are usually more severe than their delayed counterparts, and occur in patients who already have antibodies to RBC alloantigens when they are transfused with RBCs bearing those target antigens. The most severe acute HTRs are due to ABO incompatibility because the AB isoagglutinins are present at a substantial titer and fix complement efficiently, being largely IgM. The A and/or B antigen sites are also abundant on RBCs (typically 1-2 × 10⁶ antigen sites per cell). Antibodies to antigens in the Kell, Kidd, and Duffy systems also have been responsible for acute HTR.

Patients with an acute HTR typically present with temperature elevation, an important point, because they might initially be mistaken for a febrile-nonhemolytic transfusion reaction (FNHTR; discussed later). Nausea, vomiting, hypotension, low back pain, and substernal pressure may also signal the occurrence of acute hemolysis. Hemolysis is generally intravascular in this setting. The hemoglobin released into the plasma from the lysed RBCs is apparent as hemoglobinemia (red plasma rather than yellow) and hemoglobinuria (red urine that remains red after centrifugation). Disseminated intravascular coagulation and systemic hemodynamic instability may be triggered by the hemolysis. Together with the direct toxic effects of cell-free hemoglobin on the tubular cells of the kidney, these conditions are responsible for the impaired kidney function that often accompanies acute intravascular hemolysis. Therapy is largely supportive, but preservation of renal function is critical, and is often accomplished through the use of intravenous hydration and diuretics.

Delayed HTRs occur in 2 situations. In one, the patient is exposed to a foreign RBC alloantigen by transfusion and mounts a primary immune response. As the amount of antibody in the plasma increases, hemolysis may ensue. The second situation in which a delayed response may occur is when a patient is reexposed to an alloantigen to which he or she was sensitized in the past by previous transfusion or pregnancy (anamnestic response). Even if the alloantibody to this antigen is not detectable prior to the transfusion, exposure to the alloantigen can stimulate an anamnestic response. Antibodies to Kidd and Rh antigens are frequently responsible for such reactions. Hemolysis is typically extravascular in delayed HTR with the only clinical and laboratory signs being a decrease in the hemoglobin level, a rise in the bilirubin level, a low-grade temperature, and a feeling of malaise. When no hemolysis can be detected in a delayed HTR, the reaction is called a delayed serologic (rather than hemolytic) transfusion reaction.

Reactions to Plasma Components

Hypersensitivity Reactions—Allergic and Anaphylactic Transfusion Reactions

Allergic reactions occur in approximately 1% to 3% of patients receiving blood products containing plasma. In most cases, these hypersensitivity reactions are a host response to foreign plasma proteins in the donor blood components. The vast majority of these reactions consist of hives, pruritus, and erythema, and can be managed with antihistamines or steroids. More serious responses such as bronchospasm, laryngeal edema, gastrointestinal disturbance (nausea, vomiting, cramps, and diarrhea), and hypotension (anaphylactoid reaction) are much less frequent. IgA-deficient patients with anti-IgA antibodies in their plasma are at risk for serious reactions including frank anaphylaxis if exposed to IgA in a transfused blood component. If transfusion is required, these patients should be provided with components from IgA-deficient donors, or, in an elective situation, store their own components for later use. Washing packed RBC can effectively remove IgA. Patients who are IgA deficient, but who do not have anti-IgA, do not require special preparations, but should be observed closely during transfusion.
Febrile-nonhemolytic transfusion reactions are among the most common transfusion-related complications and accompany 1% to 3% of transfusions of cellular components.

White Blood Cell Reactions

Febrile-nonhemolytic Transfusion Reactions

These reactions are among the most common transfusion-related complications and accompany approximately 1% to 3% of transfusions of cellular components. They are more common in multiply transfused patients and with nonleukoreduced cellular components. An FNHTR usually presents with a temperature elevation of 1°C or more, during or shortly after a transfusion (usually within 1-2 hours), that is unlikely to be associated with the patient's underlying disease or therapy. The temperature elevation is often accompanied by chills, rigors, and generalized discomfort, and in some patients, nausea and vomiting as well. The majority of these reactions are mild and do not persist for more than 8 hours. Antipyretics may be administered, and occasionally meperidine may be required to treat severe rigors. These reactions have long been considered to be the product of antileukocyte antibodies present in the recipient’s plasma, reacting with WBCs or WBC fragments in the transfused product. There may, however, be other etiologies for the FNHTRs, including the presence of cytokines released by lymphocytes in the donated unit during storage.

Transfusion-associated Graft Versus Host Disease (TA-GVHD)

Immunocompetent T lymphocytes present in cellular blood components may engraft in an immunoincompetent transfusion recipient, particularly if cellular immunity is compromised. The engrafted, allogeneic T cells mount an alloimmune response to cells in the skin and gastrointestinal tract, similar to what occurs in hematopoietic stem cell transplant-associated GVHD. However, in transfusion-associated GVHD, the donor T cells attack the host cells in the bone marrow as well, making this complication of transfusion lethal in most cases. Fortunately, T lymphocytes in cellular blood components can be inactivated by exposure to gamma irradiation, which effectively prevents this complication. Patients at risk for this rare complication include those undergoing hematopoietic progenitor cells (HPC) transplantation or who have hematologic malignancies. Low-birth-weight infants, infants born with hemolytic disease of the newborn, and fetuses receiving intrauterine transfusions are also at risk. Patients with congenital T-cell immunodeficiencies (e.g., Wiskott-Aldrich and diGeorge syndromes) have also developed this complication. Cellular components from blood relative donors are also routinely irradiated to prevent TA-GVHD that may occur in the circumstance when the donor is homozygous for an HLA haplotype shared with the transfusion recipient. In this situation, the transfused T cells remain immunologically invisible to the otherwise immunocompetent host and, rather than being cleared, they engraft and attack the host because they recognize the mismatched host haplotype antigens as foreign. Most of the reports of TA-GVHD in other patients, such as those with solid tumors or who were undergoing surgery, predate the awareness of this 1-way haplotype match, which is the most likely explanation for the occurrence of this event in these immunocompetent patients.

Transfusion-related Acute Lung Injury (TRALI)

TRALI is characterized by the development of acute respiratory distress, hypoxia, and bilateral infiltrates on chest x-ray, often accompanied by fever and hypotension, during or within 6 hours of completion of a transfusion. To meet the current working definition of TRALI, there must be no preexisting form of acute lung injury or other risk factors such as sepsis, aspiration, or pneumonia. Most patients recover completely with supportive care, which may include mechanical ventilation, and the pulmonary infiltrates usually resolve within 2 to 4 days without long-term sequelae. However, there is a 5% mortality rate. This complication has been attributed to the presence of antileukocyte antibodies in the plasma of donor blood (often from females with a history of pregnancy) that react with the recipient’s WBCs. This results in the formation of immune complexes that are trapped in the pulmonary vasculature and lead to alveolar edema. At present, various steps are being taken to reduce the incidence of TRALI, including making FFP from predominately male donors or donors with no history of pregnancy or transfusion, or by testing for HLA antibodies.

Platelet Reactions

Posttransfusion Purpura (See the Section “Bleeding Disorders” in Chapter 11)

This rare complication occurs in patients who lack a common platelet antigen (often HPA-1A) and have developed an alloantibody by exposure through prior transfusion or pregnancy.
When reexposed to HPA-1A by transfusion of a platelet product or an RBC product containing contaminating platelets, these patients appear to develop an anamnestic response and become severely thrombocytopenic 7 to 10 days later. Paradoxically, the patient's own platelets, which are HPA-1A negative, are also cleared. Several explanations have been offered including the observation that there is an initial IgM response that reacts with GP IIb–IIIa (essentially a platelet autoantibody) but then “matures” with the production of an IgG with anti-HPA-1A specificity. The reaction is self-limiting, but may be complicated by severe hemorrhage. Steroids and intravenous immunoglobulin have been used successfully to manage this immunologic reaction.

**Refractoriness to Platelet Transfusions**

Patients may become sensitized to leukocyte and platelet antigens through transfusion or pregnancy. Transfused platelets may be cleared rapidly when given to a patient who has preformed antibodies directed at foreign platelet antigens or HLA Class I molecules, which are also expressed on the platelet membrane. As a result, it may be extremely difficult to elevate the platelet count in such patients. A patient is considered to be refractory to platelet transfusion if the increment measured between 15 and 60 minutes after the platelet transfusion is lower than expected on 2 occasions. Note that counts done several hours afterward are not useful for determining which patients are immunologically refractory. The posttransfusion count may be corrected for the number of platelets administered and the patient’s body surface area (the “corrected count increment”) as follows:

\[
\text{Corrected count increment} = \frac{\text{Platelet count increment} \times \text{Body surface area} \times 10^{11}}{\text{Number of platelets transfused}}
\]

Here the default for number of platelets transfused is: 1 unit whole blood-derived platelets = 5.5 \times 10^{10} platelets; 1 unit apheresis platelets = 3 \times 10^{11} platelets.

A corrected count increment of <7500 is a strong evidence of immunologic refractoriness. Note that other causes of refractoriness should be ruled out, among them: active bleeding, fever, sepsis, splenomegaly (splenic sequestration), disseminated intravascular coagulation, marrow transplantation, antibiotics (eg, vancomycin), IV amphotericin B, thrombotic thrombocytopenic purpura, idiopathic or immune thrombocytopenic purpura, and heparin-induced thrombocytopenia.

Patients with immunologic refractoriness may respond well to platelets from donors who lack the HLA antigens corresponding to the patient’s HLA alloantibodies (or to platelets that are HLA matched) or to platelets that have been chosen by platelet crossmatching.

Leukocytes in the transfused unit appear to be necessary for stimulating the immune response to both platelet and leukocyte antigens. Alloimmunization may be prevented by transfusion of cellular components from which leukocytes have been removed, usually by passage of the product through a filter that retains the leukocytes. Patients who are likely to need extensive platelet transfusion support (eg, for HPC transplants or hematologic malignancies) often receive leukoreduced cellular components to reduce the likelihood of alloimmunization.

**Nonimmunologic Reactions**

**Complications Created by the Physical Characteristics of Blood**

**Hypothermia**

Transfusion of small volumes of cold blood may be associated with minor discomfort. This complication can be averted by using blood warmers or blankets. In the setting of massive transfusion, however, the rapid transfusion of large amounts of blood that is at 1°C to 10°C contributes to hypothermia. Hemostasis is impaired when the circulating blood is below 37°C and in extreme situations, cardiac dysrhythmias and arrest may occur. In this setting, the use of high-throughput blood warmers is warranted.

**Transfusion-related acute lung injury** is characterized by the development of acute respiratory distress, hypoxia, and bilateral infiltrates on chest x-ray, often accompanied by fever and hypotension, during or within 6 hours of completion of a transfusion.
Chemical Complications

Iron Overload
Each unit of packed RBC contains approximately 200 mg of iron. Chronic RBC transfusion can overwhelm the body’s mechanisms for eliminating excess iron, resulting in iron accumulation in various tissues. An individual who has received 100 or more units of RBCs (20 g of iron) is at risk to develop various complications of iron overload including cardiac dysrhythmias, pancreatic failure (“bronze diabetes”), and liver function abnormalities. Tissue iron can be mobilized and excreted using chelating agents such as desferroxamine or deferasirox. Chelation therapy is a slow process and is more effective if deployed well before tissue accumulation of iron is extensive.

Potassium Toxicity
Potassium leaks out of RBCs during storage as ATP levels decline and the ATPase-dependent Na’/K’ pump activity diminishes. Once the banked RBCs are transfused, they transport glucose, restore their ATP levels, and take up the K’ that was lost during storage. In the short term, however, each unit of RBCs might contain as much as 6 mmol of extracellular K’ at the time of expiration. There have been a handful of reports of neonates, or patients with renal failure receiving large volumes of banked blood, who have developed life-threatening cardiac dysrhythmias. Neonates usually receive RBC units that have been stored for less than 1 week and have not yet accumulated much extracellular K’. Washing RBC is also an effective means of removing extracellular K’, although it is very rarely required.

Citrate Toxicity
Citrate is the anticoagulant used in the collection of all blood products and is therefore transfused with the blood product into the patient. It is present in the plasma. Hence, most of it ends up in platelet and plasma products while there is relatively little in RBC products. Citrate is metabolized by every nucleated cell of the body, but in circumstances where large volumes of banked blood are being infused rapidly, as in massive transfusion, the rapid influx of citrate may overwhelm the body’s metabolic capacity, leading to an accumulation in the patient’s plasma. Most patients can receive up to 1 unit of FFP every 6 minutes without evidence of citrate toxicity. Patients with liver failure metabolize citrate more slowly, however, and are particularly susceptible. The accumulating citrate chelates calcium, causing the ionized calcium levels to drop and producing perioral tingling and extremity paresthesias. In extreme circumstances, it may produce severe hypo(ionized)calcemia that can lead to cardiac dysrhythmias.

Depletion of 2,3-Diphosphoglycerate (2,3-DPG)
With increasing storage time of RBCs, the intracellular level of 2,3-DPG decreases, producing a left shift of the oxyhemoglobin dissociation curve. Once banked RBCs are transfused, they restore the levels of 2,3-DPG over a period of 24 to 48 hours. It has been suggested that the high oxygen affinity of the hemoglobin in the 2,3-DPG-deficient banked RBCs might impair oxygen delivery, particularly to neonates. As a result, it has become a general practice to transfuse neonates with RBCs that have been banked less than 1 week. However, most of the literature demonstrating unfavorable outcomes for neonates receiving older units was based on studies with RBC storage systems in which maintenance of 2,3-DPG levels was not as effective as it is using the current systems.

Infectious Complications (See the Section “Infectious Disease Testing”)

The Classic Pathogens
Transfusion transmission of the hepatitis viruses and the retroviruses has been substantially reduced through the interventions of donor education, screening on the basis of medical history and risk behaviors, and testing. Transfusion transmission of the hepatitis viruses and the retroviruses has been substantially reduced through the interventions of donor education, screening on the basis of medical history and risk behaviors, and testing, including the use of highly sensitive techniques based on amplification of viral genetic nucleic acids. The residual risk of HIV or HCV infection through transfusion is in the range of 1 event per 1 to 2 × 10^6 units transfused. Viral transmission by pooled plasma products has also been largely eliminated by the use of robust viral inactivation techniques or replacement with recombinant proteins.

The Current Significant Pathogens
At the present time, bacterial contamination of blood components is the most significant infectious complication of transfusion in developed countries, in terms of both the number of...
transmitted infections and the number of fatalities. It has been estimated that in the United States, approximately 1 in 500,000 units of RBCs, or 1 in 10,000 to 20,000 units of platelets, is associated with transfusion-transmitted sepsis. The organisms most frequently associated with septic RBC transfusions are psychrophilic gram-negative bacteria such as *Yersinia enterocolitica* and *Pseudomonas* spp., as well as *Enterobacter* spp. and *Serratia* spp. Platelet units have been reported to transmit gram-positive cocci (*Streptococcus aureus*, *S. epidermidis*, and *Staphylococcus* spp.) as well as gram-negative organisms (*Klebsiella* spp., *Serratia* spp., *Salmonella* spp., and *Enterobacter* spp.). The sources of these bacteria are thought to be skin commensals picked up and introduced into the blood donation with the venipuncture, or less commonly, cryptic bacteremia in clinically healthy donors. Even if the inoculum is quite small, blood provides a superb culture medium, particularly when stored at room temperature, as is the case for platelets. Although donors are now questioned specifically about antibiotic use, the health history is neither a sensitive nor a specific screening tool. The implementation of tests to screen platelet products for evidence of bacterial contamination was discussed above and is now routine.

Cytomegalovirus (CMV) is a ubiquitous member of the herpes virus family to which approximately 30% to 60% of adults in developed countries have been exposed. CMV can be transmitted by transfusion of blood components that contain leukocytes, such as packed RBCs and platelets. Although primary infection rarely produces serious disease in immunologically intact hosts, it is associated with systemic infection in immunocompromised patients who are CMV-seronegative. The following groups of patients have been shown to be susceptible to transfusion-transmitted CMV primary infection and disease and should receive CMV reduced-risk cellular blood components:

1. Premature, low-birth-weight (<1200 g) neonates
2. CMV-seronegative pregnant women (including those undergoing intrauterine transfusions)
3. CMV-seronegative recipients of, or candidates for, hematopoietic or solid organ transplants
4. CMV-seronegative, HIV-infected patients

CMV reduced-risk blood components can be obtained by screening donors for CMV antibody (IgG) that indicates past exposure, or by removing the leukocytes that contain latent CMV by filtration with leukocyte reduction filters. These 2 approaches have been shown to be equally effective in preventing transfusion-transmitted CMV infection. Only cellular components need to be CMV reduced-risk, since intact mononuclear cells are required to transmit CMV.

**Emerging Pathogens**

The blood supply will always be vulnerable to the introduction of new pathogens into the donor population. In some instances, the pathogen may truly be a new organism, or one that has recently acquired the ability to infect humans, such as the SARS virus, various strains of avian flu, and the bovine prion responsible for variant Creutzfeldt–Jakob disease. Population shifts in response to natural or man-made catastrophes, or simply travel for business or pleasure, spread pathogens from 1 part of the world to another, such as the West Nile virus, *Plasmodium* spp., and *Trypanosoma* spp. In some circumstances, questioning donors about exposure to a pathogen or a history of a characteristic illness, or the rapid development of a screening test has been an effective means of interdicting transfusion transmission of a new infectious agent. However, an effective response is more difficult in the circumstance where the organism has not been identified, its biology is unique, the routes of transmission are not well understood, or the clinical effects are not well defined. As a result, work continues to develop pathogen inactivation technology that would be suitable for cellular blood components.

**Transfusion Reaction Workup**

If a reaction is suspected, the transfusion must be stopped immediately while maintaining venous access, and the patient must be assessed. Emergent airway and hemodynamic issues should be dealt with immediately and appropriate measures taken to alleviate the patient’s major symptoms and concerns. If the assessment reveals that the patient's only symptoms are cutaneous manifestations of hypersensitivity (flushing, pruritus, and urticaria), then the transfusion may be resumed under careful observation. In all other situations, the transfusion of that unit should be stopped and a clerical check should be performed to verify that the correct unit (ie, one labeled for that patient) has been administered. A transfusion reaction form should be filled out and a
new blood bank specimen should be drawn from the patient. The transfusion reaction form, the unit involved, and the new specimen should be returned to the blood bank for evaluation. A post-transfusion urine specimen should also be obtained and sent for urinalysis.

The blood bank will perform a clerical check, and compare the posttransfusion specimen with the pretransfusion specimen used for compatibility testing for the appearance of hemolysis or hyperbilirubinemia. The ABO and Rh type of the posttransfusion specimen will be determined to confirm that the pretransfusion specimen was indeed from this patient and that the ABO and Rh type of the unit that was being transfused was appropriate. A direct antiglobulin test is also performed on the posttransfusion specimen looking for antibody-coated RBC (ie, donor cells coated with recipient alloantibody) indicating an immune-based HTR. Any findings suggestive of an HTR trigger a more extensive investigation in the blood bank. If the workup rules out a hemolytic reaction, transfusion may resume.

ALTERNATIVES TO ALLOGENEIC TRANSFUSION

The 1980s saw the considerable development of techniques to avoid allogeneic transfusion (transfusion with someone else’s blood), particularly in elective surgery. The major driver was concern about the infectious complications of transfusion. Before the development of a screening test in 1985, HIV transmission rates may have been as high as 1 in 10,000 units transfused, while as many as 5% to 10% of transfusion recipients developed what was then called non-A, non-B hepatitis, and is now known to have been due primarily to HCV, which was only identified in 1989. Although demand for these blood-sparing techniques is not as great as it was 20 years ago, they are still in use and continue to be helpful for patients with unusual blood types or multiple alloantibodies for whom it is difficult to find compatible blood. In addition, the drive to avoid allogeneic blood exposure has reinforced common sense measures: treatment of medically correctable anemia, greater physician tolerance of asymptomatic anemia, meticulous surgical hemostasis, and the wider use of hemostatic medications. The licensing of recombinant erythropoietin also reduced the dependence of patients with renal failure, malignancies, and HIV infection on regular RBC transfusion.

Four techniques in particular were developed to reduce the dependence of surgical patients on banked RBC: preoperative autologous blood donation (PABD), acute normovolemic hemodilution (ANH), intraoperative blood recovery and reinfusion, and postoperative blood recovery and reinfusion.

PABD is suitable for patients undergoing elective surgical procedures for which RBC transfusion is commonly required, and in this setting can reduce allogeneic blood use. Since the blood may only be used by the donor/recipient, donor qualifications are simple and no testing (other than ABO/Rh typing) is required. Note that mistransfusion, bacterial contamination, and volume overload are just as likely to occur with an autologous unit as with an allogeneic unit. Since the hazards averted (especially infection) are very small, donors who might be put at even a small risk by donation (eg, mild anemia and coronary artery insufficiency) should be discouraged from PABD.

ANH is a technique whereby several units of blood are removed from a patient in the operating room immediately before a procedure. The volume is replaced with crystalloid. The blood is returned if bleeding occurs, or at the end of the procedure. It has the advantage that little advance planning is necessary, but it is not very efficacious at reducing allogeneic RBC transfusions for patients with moderate anemia from whom few units can be withdrawn at the beginning of the procedure.

Blood recovered from the operative field can be collected, processed in some manner, and reinfused. Shed blood is collected by suction into a reservoir, usually with heparin or citrate, and then usually washed in a centrifugal device specially designed for this purpose. The washed RBCs are suspended in normal saline and pumped into a bag suitable for reinfusion to the patient. The washing procedure removes materials that might cause reactions such as cell debris, activated clotting factors, and complement. A similar process can be carried out manually. This technique is particularly helpful in procedures where large volumes of blood are lost. Although somewhat expensive, the recovery of 3 to 4 units of RBCs is usually adequate to recover the costs. This technique is suitable for elective as well as emergency procedures during which blood loss is extensive.

Devices are also available for collecting blood shed in the postoperative period. Many of them rely on filtration of the shed blood. The filtration technique is not adequate to remove materials that can provoke a reaction and is generally not worth risking for the small amounts of blood.
that can be recovered. A small, centrifugal device that washes the blood collected postoperatively is also available. Although it provides a much cleaner product, the small volumes of blood recovered in this manner do not make it very cost-effective.

**CELLULAR THERAPIES**

Cellular therapies encompass the collection, processing, storage, and therapeutic use of hematopoietic cells, most commonly HPCs. In addition, mononuclear cell fractions from HPC donors have been used to enhance the graft versus tumor effect of allogeneic transplantation, and dendritic cells sensitized to tumor antigens have been used to treat solid tumors. Allogeneic HPCs have the advantage that they are free of malignancy and may have a significant graft versus tumor effect; they are preferred for most forms of leukemia, Hodgkin disease, and the myelodysplastic syndromes. Allogeneic transplantation has also occasionally been used to treat certain genetic disorders of the hematopoietic system, such as sickle cell disease and thalassemia. Autologous HPC transplants are not complicated by rejection and have a lower incidence of GVHD. They are performed in patients with some forms of non-Hodgkin lymphoma and multiple myeloma, and as rescue therapy after intensive chemotherapy for some solid tumors (eg, testicular, breast, and ovarian cancer).

Potential allogeneic donors must in general meet the criteria for blood donation, including infectious disease testing, although some of these criteria may be waived if an alternate suitable donor cannot be found. Potential donors must be typed for HLA Class I and II antigens using molecular techniques. Class I mismatches pose an increased risk for rejection and failure to engraft, whereas Class II mismatches are associated with increased incidence of GVHD. A single Class I or II mismatch usually has little impact on survival. Two Class I mismatches, or a Class I and a Class II mismatch, are usually associated with poorer outcomes. Haploidentical sibling donors have been used successfully. If a suitable family member donor cannot be found (and only 1 in 4 siblings is likely to be a 2 haplotype match), a donor may be sought through the National Marrow Donor Program, a registry of people who have been HLA typed and have expressed a willingness to donate HPCs. The search may take a few months and is less likely to be successful for patients with unusual phenotypes. There has been considerable effort in the last few years to register donors from previously underrepresented minority populations. ABO or Rh matching is not necessary since the transplant recipient will convert to the donor type if engraftment is successful, although RBC engraftment may be delayed if donor RBCs are incompatible with the recipient’s anti-A or anti-B isoagglutinins. Donor isoagglutinins may also cause hemolysis of residual recipient RBCs, or at least a positive direct antiglobulin test. The conversion from recipient to donor blood type does pose problems for the transfusion service that must provide blood that is compatible with both donor and recipient until the recipient’s original RBCs and isoagglutinins are undetectable.

HPCs may be collected from peripheral blood by apheresis, from bone marrow by aspiration, or from cord blood. Apheresis collection now accounts for 90% of autologous transplants, and 50% of allogeneic transplants, a fraction that is increasing. Bone marrow aspiration is performed with multiple punctures and aspirations of the posterior iliac crest and must be performed in the operating room with the donor under general anesthesia. The aspirates are anticoagulated (heparin or citrate), filtered, and pooled into a bag that is then usually stored frozen until the time of the transplant.

Collection by apheresis is less invasive and less likely to recover residual malignant cells. In addition, it has been shown to be associated with quicker engraftment, although chronic GVHD is somewhat more likely to occur than with marrow transplantation. The number of HPCs in the peripheral blood is ordinarily very low, so donors are prepared by the administration of granulocyte colony-stimulating factor or granulocyte–macrophage colony-stimulating factor at the point when their marrow is rebounding from a cycle of chemotherapy. Under these circumstances, the levels of HPCs (which can be determined by measuring the number of CD34-positive cells in the peripheral blood by flow cytometry) may be elevated 200- to 1000-fold. The pheresis instrument is configured to collect the mononuclear cell fraction. Large volume collections (with 3 blood volumes processed) are typically performed, which reduces the number of procedures needed to collect the targeted number of CD34-positive cells (typically $2-4 \times 10^6$ per kg patient weight). Large volume collection may also have the effect of recruiting HPCs from the marrow during the collection.
The HPC product undergoes extensive quality control testing including ABO and Rh type, RBC and WBC counts (and differential), CD34 cell count, an assay to enumerate colony-forming units in vitro, cell viability, and testing for bacteria, fungi, and mycoplasma. Products are frozen (usually at a controlled rate) in the presence of 10% dimethylsulfoxide and 10% protein (plasma or albumin) as cryoprotectants, and stored in mechanical freezers or liquid nitrogen tanks. At the time of transplant, the units are thawed at 37°C, usually at the patient’s bedside, and then administered intravenously, much like a conventional transfusion.

Umbilical cord blood contains high levels of circulating HPCs, and this observation has led to the development of cord blood banking. If a mother meets the criteria for allogeneic blood donation (except for hemoglobin level and recent pregnancy because she has just delivered) including the usual infectious disease testing, and there is no history of genetic diseases in the family of either parent, she may give consent for the blood to be drained from the placenta via the umbilical cord (after it has been severed or clamped off from the neonate) and then stored frozen. In addition to the usual quality control testing of the cord blood, HLA Class I and II typing is performed as well as ABO/Rh typing.

Over 5000 related and unrelated (but HLA matched) cord blood transplants have been performed since the technique was first developed in 1988. Cord blood HPCs home readily to the host bone marrow and do not seem to be as alloreactive to recipient antigen-presenting cells as HPCs from adults. In addition, the large numbers of HLA-typed cord blood samples may improve the chances of finding unrelated matches. Cord transplants are also less likely to be complicated by GVHD and infection with CMV. However, the total number of HPCs in each cord blood sample is small and engraftment is slower. This has led to the use of double cord transplants that accelerate engraftment, even though eventually 1 of the donor’s HPCs dominates.

**THERAPEUTIC APHERESIS**

Therapeutic apheresis is the process of withdrawing blood from the body, selectively removing a particular element (ie, plasma, leukocytes, platelets, or RBCs), and returning the remaining elements along with a replacement solution (crystalloid and/or colloid) to maintain isovolemia. There are several different therapeutic apheresis procedures that are designed to remove, or treat, specific components of the blood. These are described below.

**Indications for Therapeutic Apheresis**

Indications for therapeutic apheresis have been classified according to the quality of the evidence demonstrating efficacy or the lack thereof (Table 12–8). The specific disorders for which therapeutic apheresis has been evaluated as a treatment are shown in Table 12–9.

*Number in parentheses refers to specific apheresis procedure as follows: 1) therapeutic plasma exchange; 2) photopheresis; 3) cytapheresis; 4) red cell exchange; 5) selective column adsorption.

Therapeutic apheresis has been used as a treatment for numerous disorders. While it is clearly effective in some diseases, such as thrombotic thrombocytopenic purpura, the therapeutic benefit of apheresis in many other disorders is much less clear, because many of them are uncommon, and therefore it is extremely difficult to obtain information about efficacy based on large-scale, prospective, randomized clinical trials.
Plasmapheresis

In plasmapheresis (plasma exchange; see the figure in Chapter 2), blood is withdrawn from a patient and the plasma is separated from the cellular components by centrifugation or, less commonly, by filtration, in an apheresis instrument. The plasma is discarded and the cellular components are returned to the patient. Liters of abnormal plasma can be removed from the patient and replaced by saline, albumin, starch solutions, FFP, or combinations of these. This technique is used to remove autoantibodies, immune complexes, paraproteins, and protein-bound toxins.

Cytapheresis

Cytapheresis is the removal of one of the cellular elements of the blood. Leukapheresis is occasionally indicated for patients with acute myelogenous leukemia or chronic myelogenous leukemia in the accelerated phase with a high level of circulating blasts and evidence of leukostasis with pulmonary or CNS involvement. Myeloid blast forms adhere to the vascular endothelium and can impede blood flow in the lungs and the brain. The collection of peripheral HPCs and granulocytes is a variation of leukapheresis.

Plateletpheresis may be indicated in patients with myeloproliferative disorders, such as essential thrombocythemia, who develop platelet counts that exceed 1 × 10^6/μL and also show signs of hemorrhage or thrombosis.

Erythrocytapheresis (RBC Exchange)

Although most sickle crises are managed with hydration, pain medication, and supplemental oxygen, RBC exchange is occasionally performed for patients who are experiencing a severe infarctive crisis complicated by stroke, acute chest syndrome, retinal infarction, or priapism. Exchange is performed less commonly to prepare patients for surgery. In the exchange replacement of sickle RBCs with normal RBCs, the usual goals are to reduce the hemoglobin S concentration to less than 30% of total hemoglobin, and to increase the hematocrit to 30%. Red cells chosen for exchange are often screened for hemoglobin S (since donors with sickle trait may be unaware of it and have a normal hemoglobin level) and may be partially phenotype matched (eg, for Kell and the Rh antigens) to prevent alloimmunization. Red cell exchange also has been used to treat patients with malaria or babesiosis who have a high percentage (eg, >10%) of RBCs infected with organisms despite adequate medical therapy, and signs of decompensation such as marked hemolysis, pulmonary involvement, CNS involvement, renal failure, or disseminated intravascular coagulation. Patients who are immunosuppressed, asplenic, or elderly seem to be particularly at risk to develop complications from infection with Babesia.

Photopheresis

In this apheresis procedure, the patient’s leukocytes are separated from whole blood and exposed to ultraviolet light, usually after the patient has ingested psoralen. The psoralen/ultraviolet light-treated leukocytes are then returned to the patient. Photopheresis has been used to treat cutaneous T-cell lymphoma and has been shown to increase patient survival when compared with conventional chemotherapy. Photopheresis has also been used to treat GVHD and cardiac allograft rejection.

A portion of this chapter related to complications of transfusion appeared previously in Clinical Laboratory Reviews (a newsletter for physicians at the Massachusetts General Hospital, Boston, 1995;4:2).

REFERENCES

This page intentionally left blank
Abnormalities in white blood cells (WBCs) are nearly always quantitative (eg, too many or too few WBCs). These disorders may be neoplastic, as found in leukemia, or nonneoplastic. A qualitative or functional disorder of WBCs may accompany the quantitative disorder. Qualitative defects in WBC function with a normal WBC count occur, but they are uncommon. The approach to diagnosis of WBC disorders is shown in Figure 13–1.
A low WBC count can occur because of a decreased number of lymphocytes, granulocytes, or both.

LEUKOPENIA

Description and Diagnosis

A low WBC count can occur because of a decreased number of lymphocytes, granulocytes, or both. A number of the immunodeficiency diseases are associated with a lymphocytopenia (see Chapter 3). Granulocytopenia primarily reflects a reduction in the number of neutrophils (neutropenia) in the peripheral blood. When the number of neutrophils decreases below about 1000 neutrophils/μL, the neutropenic patient becomes susceptible to infections. These illnesses range from mild to severe, depending on the type of organism and the effectiveness of the antibiotics used to treat it. A classification of granulocytopenic disorders follows.

Defects in the production of granulocytes may be caused by:

- Diseases associated with marrow failure, such as aplastic anemia.
- Diseases in which the marrow is infiltrated by leukemic cells or by metastatic cancer cells originating from another site; the decreased neutrophil production in this setting is typically associated with defects in the production of other blood cells as well.
• Suppression of granulocyte production by exposure to certain drugs; the list of drugs that can produce neutropenia is extensive; noteworthy examples are chemotherapeutic agents used in cancer treatment and certain nonsteroidal anti-inflammatory drugs (NSAIDs).
• Vitamin B₁₂ or folate deficiency; these disorders produce a megaloblastic anemia and defective DNA synthesis in granulocyte precursors.
• Suppression of granulocyte production by neoplastic cells, for example, large granular lymphocytic leukemia.

Accelerated removal of granulocytes may be caused by:
• Immunologically mediated injury to neutrophils following exposure to drugs, with the injury occurring from an immune response on the neutrophil surface.
• Immunologically mediated injury to neutrophils as part of an autoimmune disorder; for example, Felty syndrome is a variant of rheumatoid arthritis with neutropenia, splenomegaly, leg ulcers, and the joint lesions found in rheumatoid arthritis; the neutropenia can dominate the clinical course in patients with Felty syndrome.
• Immunologically mediated injury to neutrophils that is idiopathic and not associated with any identifiable abnormality.
• Excessive destruction of granulocytes from splenic sequestration of the neutrophils in an enlarged spleen or from overwhelming infection.

NONNEOPLASTIC PROLIFERATION OF WBCs

Description and Diagnosis
An elevated peripheral WBC count is commonly found in patients with infections and other inflammatory states, such as those associated with autoimmune disorders.

Lymphocytes
Patients can develop a lymphocytosis in a variety of different conditions such as tuberculosis, acute bowel infections, and infectious mononucleosis and other viral infections.

Eosinophils
An increase in circulating eosinophils is most commonly found in patients with allergic disorders and those with asthma. An increase in circulating eosinophils is also found in patients with certain parasitic infections and in patients with dermatologic disorders such as eczema. Increases in eosinophils can also be caused by some drugs and some autoimmune disorders. Finally, increases in eosinophils can be seen in certain neoplastic conditions such as Hodgkin lymphoma and T-cell lymphomas.

Monocytes
The peripheral monocyte count is increased in a number of situations where the lymphocyte count is also increased, such as tuberculosis. Rheumatoid arthritis, systemic lupus erythematosus, and other connective tissue diseases also may be associated with a monocytosis.

Neutrophils
A mild increase in circulating neutrophils can occur without disease after strenuous exercise, during menstruation, and in the course of pregnancy. An increased neutrophil count is clinically significant when it is indicative of a bacterial infection, a neoplastic disorder, ischemia, an autoimmune disorder, or an effect of certain drugs, such as corticosteroids or epinephrine. The most frequently identified immature neutrophil in the blood when there is an increased WBC count is the neutrophilic band cell. The percentage of WBCs represented by band cells or more immature neutrophil precursors is a commonly used indicator of infection. However, band counts are poorly reproducible among medical technologists, so the current trend is to not report band counts. Other less mature neutrophil precursors can be seen in infections and other conditions where the bone marrow is attempting to produce granulocytes rapidly.
NEOPLASTIC PROLIFERATION OF WBCs

WBC neoplasms frequently involve the peripheral blood, and can result in leukocytosis. White cell neoplasms are broadly divided into 2 large categories, lymphoid (the lymphocyte lineage) and myeloid (the lineage including granulocytes, monocytes, megakaryocytes, and erythroid cells). Lymphoid disorders include acute precursor lymphoblastic leukemias (ALL) and mature B-, T-, and NK-cell neoplasms. Myeloid disorders include acute myeloid leukemias, myeloproliferative neoplasms, and myelodysplastic syndromes.

LYMPHOID MALIGNANCIES

Description and Diagnosis

The lymphoid malignancies are caused by neoplastic transformation of lymphocytes or their precursors. Lymphoid cells can be found in the lymph nodes, blood, bone marrow, spleen, and extranodal sites such as the skin, mucosae, and respiratory and gastrointestinal tracts. Lymphoid neoplasms can occur at any of these sites. Neoplasms that primarily involve the bone marrow and peripheral blood are referred to as leukemias, and those involving tissue sites are called lymphomas. However, many lymphoid malignancies can involve both tissues and the blood/bone marrow, so the leukemia/lymphoma distinction is somewhat arbitrary. The World Health Organization (WHO) classification system for lymphoid malignancies is shown in Table 13–1.

Lymphoid leukemias can correspond to precursor B or T cells or mature lymphoid cells. Precursor lymphoid malignancies are also called lymphoblastic leukemias/lymphomas. Relatively common B- and T-cell malignancies that frequently present in a leukemic phase include chronic lymphocytic leukemia (CLL)/small lymphocytic lymphoma, hairy cell leukemia, mantle cell lymphoma, Burkitt lymphoma/leukemia, T-cell prolymphocytic leukemia, T-cell large granular lymphocytic leukemia, and Sézary syndrome. Lymphoid leukemias generally present with elevated white counts (specifically lymphocytosis), and depending on the degree of bone marrow involvement, there can be decreased numbers of normal white cells, red cells, and/or platelets. Processes that involve the marrow extensively can result in the presence of myeloid and erythroid precursor cells in the peripheral blood. Leukemias are diagnosed by examination of the peripheral blood smear and bone marrow aspirates and biopsies. Additional studies such as immunophenotyping by flow cytometry, molecular diagnostic techniques, and cytogenetics are frequently used to establish a diagnosis.

When lymphoid malignancies are mostly tissue-based, they are referred to as lymphomas. Lymphomas are monoclonal, neoplastic proliferations of B, T, or NK cells. Most lymphomas are malignancies of mature lymphocytes, but precursor lymphocytic malignancies can involve tissues, and thus be classified as lymphomas. Lymphomas are divided into 2 major groups, Hodgkin lymphoma and a much larger variety of lymphomas known generically as non-Hodgkin lymphomas. The patient with lymphoma often presents with an isolated, enlarged superficial lymph node, which may be discovered accidentally on physical exam. Alternatively, the patient may have generalized lymphadenopathy. If the enlarged lymph node develops in a site where it can produce signs and symptoms, it is more likely to be discovered early in the course of disease. An example is the enlargement of lymph nodes in the mediastinum, which can impair blood flow through the large vessels in the chest and produce symptoms on that basis. In some cases, organ involvement may be the first manifestation of a lymphoma. Non-Hodgkin lymphomas, for example, may become symptomatic when there is cellular proliferation in the orbit, the gastrointestinal tract, or the skin. Involvement of the bone marrow and peripheral blood also may be an initial indicator of the presence of a lymphoma.

Lymph node biopsy is the preferred method for diagnosis of lymphoma, since it allows the pathologist to determine the overall tissue architecture and get a large sample of the cells present. Because the lymphoma may not be distributed evenly in all lymph nodes, it may be necessary to biopsy several lymph nodes to establish the diagnosis. In recent years, both fine needle aspiration and biopsy have been used more commonly to make diagnoses of lymphoma. Although fine needle aspiration does not allow optimal evaluation of tissue architecture, diagnostic procedures such as flow cytometry and/or molecular techniques can be used to render a diagnosis on minimal amounts of material.

Principal differentiating factors between Hodgkin and non-Hodgkin lymphomas are:

- **Hodgkin lymphoma:**
  (a) Proliferation of cells is typically localized to a single group of nodes such as the cervical or mediastinal nodes.
  (b) Proliferating cells spread by contiguity.
  (c) Mesenteric lymph nodes are rarely involved.

- **Non-Hodgkin lymphomas:**
  (a) Frequent involvement of multiple groups of nodes.
  (b) Proliferating cells spread widely and noncontiguously.
  (c) Mesenteric lymph nodes are commonly involved.

The Hodgkin and non-Hodgkin lymphomas are classified into clinical stages based on the distribution of the disease. These stages, with increased clinical severity associated with higher stage numbers, are as follows:

- **Stage I**—involvement of 1 group of lymph nodes or 2 contiguous lymph node clusters on the same side of the diaphragm.
- **Stage II**—involvement of 2 or more noncontiguous lymph node groups on the same side of the diaphragm.
- **Stage III**—lymph node involvement above and below the diaphragm; if there is involvement of the spleen, the lymphoma is classified as III(s); and if there is visceral involvement by direct extension, it is known as stage III(e).
- **Stage IV**—widespread disease, often involving the liver, bone marrow, lungs, bones, and skin.

In addition to the above staging scheme, the designation “B” is added for patients who have constitutional symptoms such as fever, night sweats, and weight loss. For example, a patient with involvement of 2 groups of lymph nodes on the same side of the diaphragm with fevers and night sweats would be considered stage IIB. In general, the presence of these “B symptoms” portends a more advanced stage of disease with worse prognosis. In addition, the designation “E” is used to designate lymphomas involving extranodal sites only (eg, the gastrointestinal tract).

**Lymphoma**

Historically the diagnosis of Hodgkin and non-Hodgkin lymphoma was primarily based on the histological appearance of the lymph nodes. For Hodgkin lymphoma, the Rye classification system was used for decades and has now been incorporated with relatively few changes into the current WHO classification system for hematologic malignancies. Classification of non-Hodgkin lymphomas has been more problematic. Non-Hodgkin lymphomas were organized in the Rappaport classification in 1966, the Lukes–Collins classification in 1973–1974, and in 1982 they were reclassified according to the Working Formulation of Clinical Usage by an international panel of experts.

By the early 1990s, significant progress was made in understanding the biology of lymphomas, so newer classification systems were developed based on typing lymphomas with antibodies specific for cytoplasmic and cell surface proteins (immunohistochemistry and flow cytometry) and by detecting specific molecular lesions. In 1994, the REAL classification was introduced by the International Lymphoma Study Group. The goal of the new classification was to integrate morphological, immunologic, and genetic information to better define the disease entities. The REAL classification system was modified somewhat to form the basis for the current (2008) WHO classification system (Table 13–1).

The WHO classification system, like the REAL classification system preceding it, attempts to classify non-Hodgkin lymphomas according to the normal cell equivalent of the neoplastic cells. First, neoplastic cells are classified based on whether they are of B-cell or T-cell/NK-cell origin. Next, the cells are classified by the stage of differentiation to which they correspond. Most B- and T-cell neoplasms correspond to mature B and T cells.

In the end, lymphoma classification is determined by the architectural features observed under the microscope (eg, follicular vs diffuse growth pattern and the microscopic appearance of the malignant cells), the spectrum of proteins expressed on the surfaces and in the cytoplasm of the malignant cells (eg, T- or B-cell markers and proteins not expressed in normal lymphocytes),

For Hodgkin lymphoma, the Rye classification system was used for decades and has now been incorporated with relatively few changes into the current WHO classification system for hematologic malignancies. Classification of non-Hodgkin lymphomas has been more problematic.
the presence of clonal rearrangements of the immunoglobulin or T-cell receptor genes, and, in some cases, the presence of specific genetic lesions in the malignant cells. The techniques used for lymphoma diagnosis include light microscopy, immunohistochemistry, flow cytometry, and molecular techniques including cytogenetics, fluorescence in situ hybridization (FISH), polymerase chain reaction (PCR), and newer techniques such as microarrays.

Since it is beyond the scope of this chapter to discuss all the lymphoid malignancies in detail, the more common disorders have been selected for inclusion.

**Precursor B- and T-cell Neoplasms**

Neoplasms of immature B and T cells most commonly present as leukemias, with extensive blood and bone marrow involvement, but they can also involve the lymphoid tissues as lymphomas. For example, precursor T-cell leukemia/lymphoma often presents with a mediastinal mass and may not demonstrate blood or bone marrow involvement. ALL accounts for almost one third of all childhood cancers and represents 75% of all pediatric leukemias. The median age at diagnosis is 10 years with a slight male predominance of 1.4:1. Pediatric leukemias are almost always (80%-85%) of a precursor B-cell lineage, with the remainder being T-cell lineage.

**Diagnosis**

- **Morphology**—Morphologically, the involved tissues show monomorphic collections of medium-sized cells with fine chromatin, high nuclear:cytoplasmic ratios, and inconspicuous nucleoli.
- **Immunophenotyping**—Depending on lineage, the cells will express B- or T-cell surface proteins. Both B- and T-cell precursor cells contain the enzyme terminal deoxynucleotidyl transferase.
- **Cytogenetics**—There are a number of recurrent chromosomal translocations associated with ALL. Hyperdiploidy with 50 or more chromosomes is a favorable prognostic finding. The presence of the Philadelphia chromosome, t(9;22)(q43;q11), is an adverse prognostic finding.

**Chronic Lymphocytic Leukemia**

**Description**

CLL is the most common of the non-Hodgkin lymphomas. The median age at diagnosis is 70 years with a slight male predominance of 1.7:1. The neoplastic cells in CLL are mature B cells. CLL is an indolent disease with a highly variable life expectancy. Transformation to aggressive disease occurs in 5% to 10% of cases at any time during the course of the illness, and is usually a terminal event.

**Diagnosis**

- **Morphology**—The lymphocytes in CLL are usually small and well differentiated. They are sometimes difficult to distinguish from normal lymphocytes, but they can be identified by their somewhat larger size, coarsely clumped chromatin, and tendency to break apart on peripheral blood smears, forming “smudge cells.” CLL can transform into a high-grade B-cell lymphoma known as Richter syndrome in approximately 3% of B-cell CLL cases. Another type of transformation is to the prolymphocytoid form, where patients can have a very high white count of characteristic prolymphocytes with prominent nucleoli.
- **Immunophenotyping**—The CLL tumor cells express low levels of monoclonal surface IgM and IgD in the majority of cases, surface IgM only in approximately 25% of the cases, and surface IgD, other immunoglobulin isotypes, or no surface immunoglobulin in a small percentage of cases. A characteristic finding in CLL is expression of CD5, which is normally a pan-T-cell antigen, but is expressed on a minor normal subset of B cells. CLL cells also express the B-cell antigens CD19, CD20 (low level), and CD23. Immunophenotyping can also be used for prognosis: high-level expression of CD38 and ZAP-70 is associated with worse prognosis.
- **Cytogenetics**—Chromosomal abnormalities in CLL have prognostic significance. Deletions of 11q and 17p are associated with significantly shorter survival. Deletion of 13q is associated with better prognosis.
• **Molecular genetics**—As with all B-cell lymphomas, the cells of CLL have clonally rearranged immunoglobulin genes. CLL with hypermutated immunoglobulin gene regions (compared with the baseline unmutated sequences) has a better prognosis. Unmutated immunoglobulin genes are associated with worse prognosis.

### Hairy Cell Leukemia

**Description**

Hairy cell leukemia is an uncommon form of non-Hodgkin lymphoma. This disease generally occurs in men with a median age at diagnosis of 50 years. The male to female ratio is approximately 4:1. The clinical manifestations are primarily the result of infiltration of the tumor cells into the bone marrow, liver, and spleen. A significant clinical finding on physical examination is the often massive splenomegaly. The liver is also enlarged, but to a much lesser degree than the spleen. Marrow failure is common in this disease, resulting in pancytopenia and its associated complications. Patients generally present with splenomegaly, leukopenia with a relative decrease in monocytes, and an inapplicable bone marrow.

**Diagnosis**

- **Morphology**—The diagnosis of hairy cell leukemia is supported by the identification of lymphocytes with bean-shaped nuclei and fairly abundant gray cytoplasm, giving the cells a somewhat monocytic appearance. Fine cytoplasmic projections that have a hair-like appearance on Wright–Giemsa-stained smears give this entity its name.
- **Cytochemistry**—The cells in hairy cell leukemia stain positively for acid phosphatase that is partially or completely resistant to removal on the addition of tartrate. This is known as TRAP, for tartrate-resistant acid phosphatase. TRAP-positive lymphocytes with fine cytoplasmic projections are highly consistent with a diagnosis of hairy cell leukemia.
- **Immunophenotyping**—The hairy cells have a B-cell phenotype, with monoclonal surface immunoglobulin, CD19 (increased), and CD20 (increased). Antigens that are relatively specific for hairy cell leukemia include the interleukin 2 receptor alpha, CD25, as well as surface CD11c and CD103. Immunohistochemistry performed on bone marrow biopsies or spleen can be used to detect DBA44, which is relatively selective, although not specific, for hairy cell leukemia. These results are all consistent with the identification of hairy cell leukemia as a B-cell disorder.
- **Molecular genetics**—The neoplastic B cells of hairy cell leukemia have clonally rearranged immunoglobulin genes. Recently most hairy cell leukemias were found to have a mutation of the *BRAF* gene (V600E) that was previously found in melanoma. This mutation is relatively specific for hairy cell leukemia and does not appear to affect disease prognosis.

### Plasma Cell Dyscrasias

The plasma cell dyscrasias are disorders in which there is an expansion of a single clone of immunoglobulin-secreting cells. This results in the appearance of high levels of complete or incomplete immunoglobulin molecules in the serum or urine. The monoclonal immunoglobulin in the serum is known as an M-component because it is found in the prototype disorder in this group of diseases, multiple myeloma. Incomplete immunoglobulins containing only light chains or only heavy chains may be produced in certain plasma cell dyscrasias. The free light chains, which are known as Bence-Jones proteins, may be excreted into the urine. The 5 disorders included in this grouping of plasma cell dyscrasias are plasma cell myeloma, Waldenström macroglobulinemia, heavy chain disease, primary amyloidosis, and monoclonal gammopathy of unknown significance (MGUS). Amyloidosis is discussed in Chapter 3, and the other entities are described as follows.

### Plasma Cell Myeloma

**Description**

Plasma cell myeloma, also known as multiple myeloma, is a disorder resulting from proliferation of a single plasma cell clone that produces a monoclonal immunoglobulin. The median
age for presentation is 62 years. The most frequent presenting symptom is bone pain resulting from osteolytic lesions produced by clusters of plasma cells infiltrating the bone. The bones most often affected are the skull, the ribs, the vertebrae, and the long bones of the extremities. Because patients with multiple myeloma are often anemic, fatigue and weakness are common presenting symptoms. Patients may also experience recurrent bacterial infections as a result of the leukopenia that occurs later in the disease. In addition, the passage of free light chains into the urine may result in “myeloma kidney” and lead to renal failure. The diagnosis of myeloma depends on the presence of a monoclonal protein in the serum or urine, and then the type of myeloma is further classified based on the severity of the disease (Table 13–2). A skeletal survey is included in the initial workup of myeloma to assess the extent of bone involvement.

### Diagnosis

- **Morphology**—The diagnosis of plasma cell neoplasm is made when increased numbers of plasma cells are observed in a bone marrow or tissue biopsy. In the bone marrow, plasma cell numbers will be increased, and they form small clusters to extensive sheets in bone marrow biopsies. Solitary tissue lesions, often involving bone, may also show sheets of abnormal plasma cells and are classified as plasmacytomas. Abnormal plasma cells are rarely seen in the peripheral blood, and “plasma cell leukemia” is considered an end-stage presentation of this disorder.
- **Immunophenotyping**—Abnormal plasma cells can be detected by flow cytometry based on abnormal loss of CD19 and CD45, expression of CD38 and CD138, and monoclonal immunoglobulin light chain in the cytoplasm. The abnormal cells may express CD56, which is absent on normal plasma cells. In tissue sections, the abnormal plasma cells are recognized by expression of CD138 and monoclonal cytoplasmic immunoglobulin light chain expression.
- **Cytogenetics**—Chromosomal abnormalities in myeloma have prognostic significance. Most commonly FISH is used to identify specific abnormalities. For FISH, fluorescent DNA probes for the genes of interest are used to localize these genes in chromosome preparations or in cell nuclei. These probes can determine if 2 separate genes are brought together in a translocation or if a gene is broken apart by a translocation. It is helpful to use some kind of enrichment technique, such as magnetic beads coated with antibodies that plasma cells express (eg, CD138), to obtain enough plasma cells to study. Favorable risk cytogenetic abnormalities include hyperdiploidy, t(11;14) or t(6;14). Poor risk cytogenetic abnormalities include deletion of chromosome 13, t(4;14), t(14;16), t(14;20), deletion of 17p13, and hypodiploidy.  
- **Molecular genetics**—Plasma cell neoplasms have clonal rearrangements of their immunoglobulin genes.  
- **Protein electrophoresis**—The evaluation of a patient for multiple myeloma begins with protein electrophoresis of serum and urine to identify any monoclonal proteins (see Chapter 2 for protein electrophoresis and immunofixation). An M-component on an electrophoretic gel is a dense band of protein that is not usually present. It most often migrates in the gamma region of the gel, but occasionally appears in the beta or alpha-2

</tbody>
</table>
region. To increase the likelihood of M-component detection in the urine, the samples evaluated for M-components must be concentrated prior to electrophoresis. Confirmation that a band identified on serum or urine protein electrophoresis represents an M-component involves further analysis by immunofixation electrophoresis (see Chapter 2) or, much less frequently now, by immunoelectrophoresis. Both of these tests permit identification of the specific heavy chain and light chain of the M-component, if both are present. It is also necessary to quantify serum immunoglobulins to determine if the concentration of the M-component is greater than 35 g/L.

- Other chemistry tests—Beta-2 microglobulin is the light chain of a class 1 major histocompatibility complex protein, and is present on the surface of all nucleated cells. Increased levels of the unbound beta-2 microglobulin in the plasma are found in multiple myeloma and are considered a reflection of tumor burden. Other tests used to evaluate myeloma include measurement of serum calcium and evaluation of renal function.

Waldenström Macroglobulinemia

Description

Waldenström macroglobulinemia is the clinical syndrome associated with lymphoplasmacytic lymphoma in the WHO classification. There is a diffuse infiltration of the bone marrow by small lymphocytes and plasma cells that synthesize an IgM immunoglobulin, which is referred to as a macroglobulin. It is similar to plasma cell myeloma in that both have an M-component. However, the M-component in Waldenström macroglobulinemia is always an IgM molecule, and unlike the relatively rare IgM myeloma patient, individuals with Waldenström macroglobulinemia do not have lytic bone lesions. The mean age for presentation is 63 years, with a slight male predominance. Patients frequently present with fatigue, weight loss, weakness, and bleeding from anemia and thrombocytopenia. When present in sufficient concentration, the large circulating IgM protein produces a hyperviscosity syndrome in the plasma and tissue deposition of IgM. Most patients with Waldenström macroglobulinemia have an elevated serum viscosity, but only 15% to 20% are symptomatic. The most common symptoms associated with slow blood flow from hyperviscosity are blurred vision, mucosal bleeding, dizziness, and, on funduscopic examination of the eye, papilledema, hemorrhage, and distention of the retinal veins.

Diagnosis

- Morphology—The pathological correlate of Waldenström macroglobulinemia is lymphoplasmacytic lymphoma. The abnormal cells are small mature-appearing lymphocytes, some of which may resemble small plasma cells. The cells can be present in tissue biopsies, peripheral blood, or bone marrow.
- Immunophenotyping—The abnormal cells express the B cell markers CD19 and CD20 without coexpression of CD5 or CD10. The cells will have surface expression of monoclonal immunoglobulin. The abnormal cells may express plasma cell antigens such as CD38 or CD138.
- Protein electrophoresis—The diagnosis of Waldenström macroglobulinemia requires demonstration of an IgM serum protein concentration greater than 30 g/L. As with multiple myeloma, Waldenström macroglobulinemia must be differentiated from an IgM MGUS.
- Molecular genetics—Recently a mutation in the MYD88 gene (L265P) has been found to be specifically associated with Waldenström macroglobulinemia.

Heavy Chain Disease

Description

The heavy chain diseases are a group of lymphoproliferative disorders in which there is production of monoclonal immunoglobulins with only heavy chains. Each type of heavy chain disease is named for the abnormal heavy chain produced, resulting in:

- Alpha chain disease—a high serum concentration of the heavy chain present in IgA
- Gamma chain disease—a high serum concentration of the heavy chain present in IgG
- Mu chain disease—a high serum concentration of the heavy chain present in IgM
All the heavy chain diseases are rare, with alpha chain disease having the highest incidence of the related disorders. In all 3 disorders, the monoclonal heavy chain is defective with internal deletions of most of the variable region of the protein and some portion of the first constant region domain. Common clinical findings in patients with heavy chain disease are splenomegaly, hepatomegaly, and lymphadenopathy. Almost all cases of mu chain disease have been associated with CLL. Gamma chain disease has been found in the presence of a variety of autoimmune disorders and in lymphoplasmacytic lymphoma. Alpha chain disease is associated with extranodal marginal zone lymphoma of the MALT type, which usually involves the gastrointestinal tract.

**Diagnosis**
The diagnosis of heavy chain disease is made primarily by demonstration of a monoclonal heavy chain by protein electrophoresis of serum, concentrated urine, or both. The diagnosis of heavy chain disease should prompt an investigation into the presence of lymphoma if that diagnosis has not already been made.

**Monoclonal Gammopathies of Unknown Significance**

**Description**
Patients with MGUS are asymptomatic but have a monoclonal protein in their serum and/or urine. There is an increasing incidence of MGUS with aging. Because the incidence of malignant monoclonal gammopathies also increases with age, it is essential to differentiate patients who have MGUS from those who have plasma cell myeloma or Waldenström macroglobulinemia. Most patients with MGUS remain clinically stable without therapy for many years. However, as many as 15% to 20% develop myeloma, macroglobulinemia, amyloidosis, or lymphoma. Indolent myeloma and smoldering myeloma, disorders with many features of multiple myeloma and Waldenström macroglobulinemia that do not meet the criteria for diagnosis, can be differentiated from MGUS because MGUS has a lower amount of immunoglobulin in the serum and a lower percentage of plasma cells in the bone marrow.

**Diagnosis**
MGUS is diagnosed by the presence of a monoclonal serum or urine immunoglobulin at a concentration less than that required for a myeloma diagnosis, less than 10% abnormal plasma cells in the bone marrow, no lytic bone lesions, and no symptoms suggestive of multiple myeloma.

**Hodgkin Lymphoma**

**Description and Diagnosis**
Hodgkin lymphoma is distinguished from non-Hodgkin lymphoma by the presence of a neoplastic giant cell known as a Reed–Sternberg cell in the lymph node. For many years the lineage of the Reed–Sternberg cell was controversial, but the best information now indicates that the Reed–Sternberg cell is an abnormal malignant B cell. Hodgkin disease is a common form of malignancy in young adults with a second peak incidence in older individuals. Unlike the multiple classification schemes for non-Hodgkin lymphomas, a classification of Hodgkin disease known as the Rye classification was accepted for decades. This classification system has now been incorporated with minor changes into the WHO classification system for hematologic malignancies. Hodgkin lymphoma is divided into 2 broad categories: classical Hodgkin lymphoma and nodular lymphocyte-predominant Hodgkin lymphoma. Classical Hodgkin lymphoma is characterized by infrequent Reed–Sternberg cells in a background of normal lymphocytes, plasma cells, eosinophils, and granulocytes. The Reed–Sternberg cells lack expression of the pan-hematopoietic marker CD45; they occasionally express the B-cell marker CD20, and they characteristically express CD30 and CD15. The different subtypes of classical Hodgkin lymphoma in the WHO classification are characterized primarily by differences in tissue architecture and the composition of the cellular background.

Nodular lymphocyte-predominant Hodgkin lymphoma also shows scattered large abnormal cells, but these do not have the appearance of Reed–Sternberg cells. The abnormal cells in
nodular lymphocyte-predominant Hodgkin lymphoma have convoluted nuclei, leading to the term “popcorn cells.” These abnormal cells express the pan-hematopoietic marker CD45 and the B-cell marker CD20; they variably express CD30 and do not express CD15. The abnormal cells are frequently ringed by normal T cells. Nodular lymphocyte-predominant Hodgkin lymphoma is best thought of as a low-grade B-cell lymphoma.

**MYELOID DISORDERS**

**Acute Myeloid Leukemias**

Acute leukemias are hematologic malignancies that primarily involve the peripheral blood and bone marrow. An acute leukemia is a neoplasm of a hematopoietic stem cell that has lost its capacity to differentiate and regulate its own proliferation. The outcome of the expansion of the leukemic clone is an accumulation of poorly differentiated WBC precursors known as blasts in the bone marrow. These limit the production of normal blood cells. The blasts commonly appear in the peripheral blood and permit identification of an acute leukemia from review of the peripheral blood smear. A diagnosis of acute leukemia requires that 20% or more of the bone marrow cells be blasts. These disorders are usually rapidly progressive, and patients can die within days to weeks without therapeutic intervention. In the WHO classification, leukemias are not considered an independent group of diseases. Instead, they are classified according to their cell of origin. Acute leukemias of lymphoid cells are included in the B- and T-cell malignancy classification scheme. In this section, we will consider the acute myeloid leukemias, which are malignancies of myeloid stem and precursor cells.

Leukemias cannot generally be diagnosed by morphology alone. In particular, it is frequently not possible to distinguish leukemias of myeloid lineage from leukemias of B- or T-cell precursors. Special cytochemical stains can sometimes help identify the lineage of the leukemic cells, but definitive classification is best done by immunophenotyping using flow cytometry. It is also important to perform cytogenetic and/or molecular analysis of leukemias, to obtain prognostic information and, in some cases, information that can be used to design specific therapy. The description and diagnosis for several acute leukemias are presented in the sections that follow.

A uniform classification for the acute leukemias was developed in 1976 by the French–American–British (FAB) cooperative group. The classification from the FAB cooperative group ultimately divided AML into 7 types, M1 to M7. These types were based primarily on the morphology of the leukemic blasts and in some cases on cytochemical staining. In 1990, the National Cancer Institute established guidelines for an M0 type of AML that is not within the M1 to M7 classification. The distinction between AML and the myelodysplastic syndromes was clarified at that time (see the section “Myelodysplastic Syndromes”). As more has been learned about the molecular pathophysiology of AML, it has become clear that the FAB categories do not correspond to distinct biological entities. For example, the translocation t(8;21) can be found in several different FAB types. The one exception is FAB type M3, acute promyelocytic leukemia. This leukemia reproducibly has a translocation t(15;17), and is unique among the myeloid leukemias in its response to treatment by all-trans retinoic acid or arsenic trioxide.

The 2008 WHO classification system recognizes some of the drawbacks of the FAB system. New features of the WHO system include defining specific leukemias by their molecular pathology for those with recurrent chromosomal abnormalities, and creating categories for leukemias evolving from previous myelodysplastic syndromes and from patients treated with leukemogenic chemotherapy for prior malignancies that do not fit neatly into the FAB categories (see Table 13–3). For the remaining myeloid leukemias (“not otherwise specified”), classification is similar to the FAB system (see Table 13–4).

**Leukemias With Recurrent Genetic Abnormalities**

Certain common chromosomal translocations are found in acute myeloid leukemia. These translocations usually result in the generation of an abnormal transcription factor that alters gene expression, leading to leukemia. The most common recurrent translocation is the t(8;21) (q22;q22) involving the genes RUNX1–RUNX1T1. It is seen in several FAB types of AML and is
associated with a relatively good prognosis. The inv(16) translocation involves the genes \textit{CBFB–MYH11} and is associated with a type of myelomonocytic leukemia that has increased eosinophils in the bone marrow (FAB type AML M4-Eo). It is also associated with a relatively good prognosis. The t(15;17) translocation involves the genes \textit{PML–RARA} and is uniquely associated with acute promyelocytic leukemia (FAB type M3). This translocation results in an abnormal form of the retinoic acid receptor \( \alpha \) (\textit{RARA}). Interestingly, acute promyelocytic leukemia can be treated with all-\textit{trans} retinoic acid in addition to standard leukemia chemotherapy, and many patients have a good outcome. The all-\textit{trans} retinoic acid presumably interacts with the abnormal product of the t(15;17) fusion gene and interferes with its leukemogenic function. This was the first acute leukemia therapy described that was directed at the molecular pathology of the leukemia. Another recurrent chromosomal abnormality associated with AML is the t(9;11) involving the genes \textit{MLLT3–MLL}, the latter of which is at chromosome 11q23. In addition to \textit{MLLT3}, \textit{MLL} forms fusion genes with many different partner genes. It is found more commonly in pediatric AML and is associated with a somewhat worse clinical outcome. Rarer translocations that are defined entities in the WHO classification include t(6;9)/\textit{DEK–NUP214}, inv(3)/\textit{RPN1–EVI1}, and t(1;22)/\textit{RBM15–MKL1}.

Secondary Acute Myeloid Leukemia

Unlike the leukemias with recurrent chromosomal abnormalities, which are thought to represent de novo events, there is a group of leukemias that evolve out of previously existing conditions. One set consists of the leukemias that develop from patients with stem cell disorders such as the myelodysplastic syndromes (see below). These leukemias are associated with morphological abnormalities in all hematopoietic lineages. The other secondary leukemias develop in patients who have had previous chemotherapy for other malignancies. These leukemias occur in patients who were treated with alkylating agents such as cyclophosphamide or nitrogen mustard or with topoisomerase inhibitors such as the epipodophyllotoxins or anthracyclines. Both sets of leukemias are associated with complex cytogenetic abnormalities and have poor prognoses.

Other Acute Myeloid Leukemias

Leukemias that do not have characteristic cytogenetic abnormalities or documented previous stem cell disorders or therapy are characterized by their putative lineage as determined by immunophenotyping, morphology, and cytochemical staining. Their classification is most similar to the FAB system used prior to the WHO classification. The diagnostic criteria for these leukemias are shown in Table 13–4.

Biphenotypic and Mixed Lineage Leukemias

There is a subset of acute leukemias that express both myeloid and lymphoid markers at the same time on the same blasts. These are called mixed lineage leukemias. These leukemias may reflect a lack of marker specificity or aberrant gene expression by a malignant hematopoietic stem cell. Biphenotypic leukemias have separate subpopulations of leukemic blasts with different immunophenotypes (e.g., myeloid on 1 set and lymphoid on another). Both types of leukemias generally have a relatively poor prognosis.

Diagnostic Techniques for AML

- **Cytochemistry**—Two cytochemical stains are widely used in the diagnostic evaluation of an acute leukemia. These are myeloperoxidase (MPO) and nonspecific esterase (NSE). MPO identifies cells of myeloid lineage, which usually stain intensely positive for MPO. Monoblasts and promonocytes, which appear in acute myelomonocytic leukemia, can also react with MPO. NSE is confined mostly to cells of monocytic lineage, which predominate in acute monoblastic/monocytic leukemia.

- **Immunophenotyping**—With the development of monoclonal antibodies that can be fluorochrome-conjugated to bind to and identify cell antigens, flow cytometry has become a useful tool in distinguishing AML from ALL, and identifying the individual subtypes of AML. Immunophenotyping is particularly important in the identification of blasts that show no morphological features to indicate their lineage, as found in the minimally differentiated subtype of AML. Markers such as CD14 and CD64 can be useful in identification of monocytic cells in AML. The detection of hemoglobin or glycophorin A aids in the diagnosis of erythroleukemia. Identification of platelet glycoprotein antigens supports a diagnosis of acute megakaryoblastic leukemia.

- **Cytogenetics and FISH**—As described above, certain types of AML are defined by specific chromosomal rearrangements. Traditionally, chromosomal rearrangements are detected by cytogenetic studies, in which the chromosomes of dividing leukemic blasts are stained and examined under the microscope, which allows the different chromosomes to be identified, and where abnormal chromosome rearrangements can be detected. To look for specific gene rearrangements, FISH is used, which is the fastest and most sensitive method for detecting the specific rearrangements in leukemias with recurrent genetic abnormalities.

- **Molecular genetics**—Molecular genetic tests are also used to provide diagnostic and/or prognostic information not available from morphological analysis. For example, PCR gene amplification (in addition to FISH) can be used to detect the recurrent cytogenetic translocations of AML. Molecular analysis can also be used to detect mutations in specific genes such as FLT3, NPM1, and CEBPA, which frequently occur in AML with...
Laboratory Approaches for Determination of AML Prognosis

Acute myeloid leukemia is currently treated initially with one of a small number of chemotherapy regimens, all of which are quite toxic to the bone marrow and other organs. By studying large numbers of patients with AML, it has become clear that certain types of AML tend to respond well to standard chemotherapy, whereas others do poorly and require more intensive chemotherapy regimens and/or stem cell transplantation if a patient has a chance to be cured. This research has shown that cytogenetic and molecular abnormalities correlate well with prognosis, and thus the clinical laboratory has a critical role to play in determining the therapy for patients with AML: the goal is to identify those patients who need more aggressive treatment at the time of their diagnosis while sparing those with a better prognosis exposure to unnecessary and possibly life-threatening therapy.

The traditional way of determining AML prognosis has been to use cytogenetic studies to place patients into favorable, unfavorable, or intermediate risk groups (see Table 13–5). Favorable risk cytogenetics include AML with t(8;21), inv(16), or t(15;17). Unfavorable risk cytogenetics include AML lacking more than 1 chromosome, inv(3), MLL rearrangements, and AML with multiple cytogenetic abnormalities. Those meeting neither favorable risk nor unfavorable risk criteria are considered intermediate risk, including AML with no cytogenetic abnormalities.

Further information about AML prognosis has come from studying individual genes found to have an impact on a patient’s likelihood of cure with standard chemotherapy. One of the most important genes for prognosis is the \( \text{FLT3} \) gene. When this gene is mutated in AML cells, it puts a patient into an unfavorable risk category, even if the AML has other more favorable risk characteristics. In contrast, mutation of the \( \text{NPM1} \) gene confers more favorable risk if there is no \( \text{FLT3} \) mutation. Similarly, if both copies of the \( \text{CEBPA} \) gene are mutated, the patient is considered favorable risk, again in the absence of a \( \text{FLT3} \) mutation. Mutation of the \( \text{KIT} \) gene confers a poor prognosis on the t(8;12) and inv(16) AMLs, which ordinarily have a good prognosis. Currently many more genes are being recognized as having an impact on AML prognosis, and genetic analysis is likely to replace cytogenetics for determining AML prognosis. Next-generation sequencing technologies are rapidly evolving and will allow numerous genes, or even the entire genome, of AML cells to be determined, which will improve the ability to determine disease prognosis and hopefully lead to therapies that can target each individual’s unique cancer cells.

**MYELOPROLIFERATIVE NEOPLASMS**

Disorders in which there is a clonal neoplastic proliferation of a multipotent myeloid stem cell are grouped together in the myeloproliferative disorders. The major disorders in this grouping include:

- Chronic myeloid leukemia, with cell proliferation in the granulocytic series
- Polycythemia vera, in which erythrocytic precursors dominate the picture (see the section “Erythrocytosis” in Chapter 10)
- Essential thrombocythemia in which megakaryocytes are the primary cytological feature (see the section “Bleeding Disorders” in Chapter 11)
- Primary myelofibrosis (see the following), a disorder in which the bone marrow is initially hypercellular in multiple cell lineages and then gradually becomes markedly hypocellular with the development of marrow fibrosis

The myeloproliferative neoplasms have a fair amount of overlap in their clinical and hematologic findings, including increased numbers of red cells, platelets, and/or white cells, the presence of circulating immature cells, and the presence of marrow fibrosis. The fibrosis is a reactive response to the neoplastic elements of the bone marrow. Myeloproliferative neoplasms are differentiated from the myelodysplastic disorders because in the myeloproliferative neoplasms, there are few, if any, dysplastic changes in the blood cell precursors in the marrow. The prognosis of the myeloproliferative neoplasms varies depending on the diagnosis. Polycythemia vera and essential thrombocythemia tend to have very long survival and a low incidence of transformation to acute leukemia. Chronic myeloid leukemia and primary myelofibrosis have worse prognoses.

Chronic myeloid leukemia is distinct from the other myeloproliferative disorders in that it contains a specific chromosomal translocation, t(9;22)(q34;q11), also known as the Philadelphia chromosome. This will be discussed in detail below.

The other myeloproliferative disorders commonly contain a mutation in the JAK2 tyrosine kinase gene. JAK2 is a tyrosine kinase involved in transmitting growth signals for several different hematopoietic growth factors. In approximately 80% to 90% of polycythemia and in approximately 40% to 50% of essential thrombocythemia and primary myelofibrosis, the valine at amino acid 617 is mutated to a phenylalanine (designated V617F). This mutation inactivates a domain of the JAK2 protein that normally inhibits its tyrosine kinase activity. The result is that the kinase becomes activated without growth factor stimulation, and this leads to uncontrolled proliferation of the cells. Molecular testing for the V617F mutation has become standard practice for patients suspected of having a myeloproliferative neoplasm.

**Chronic Myeloid Leukemia**

**Description**

CML represents approximately 15% of all leukemias in the United States. The median age at diagnosis is 65 years, and there is a slight male predominance, with a male to female ratio of 1.7:1. In CML, the disease begins with a chronic phase that usually lasts for 3 to 4 years after diagnosis. The chronic phase evolves into a more aggressive accelerated phase of the disease. This phase persists for 1 to 2 years in most cases. At least 25% of patients with CML die in this phase of the disease. The remainder progress to an acute leukemia, which is known as blast crisis. The blast crisis typically leads to death within 6 months because it is highly resistant to chemotherapy. Approximately 25% of the patients with CML advance rapidly from chronic phase to blast crisis, without a significant intervening period of acceleration. Hematopoietic stem cell transplantation in chronic phase for patients who can tolerate the procedure is highly effective at curing CML.

CML is characterized by a characteristic chromosomal translocation, t(9;22), also known as the Philadelphia chromosome. Discovered in 1960, this was the first genetic lesion associated with a human cancer. When molecular cloning techniques became available, the t(9;22) was found to produce an abnormal RNA and protein product, BCR–ABL1. BCR–ABL1 is a tyrosine kinase that is constitutively active and leads to uncontrolled proliferation of myeloid cells. In 1996, a drug, imatinib mesylate, was discovered that inhibits the tyrosine kinase activity of BCR–ABL1, and this has led to a revolution in the treatment of CML, which previously relied primarily on interferon-alpha and bone marrow transplantation. Long-term treatment with imatinib can lead...
to drug resistance however, and new BCR–ABL1 inhibitors are in development to overcome this problem. The only curative treatment for CML is still bone marrow transplantation.

**Diagnosis**

The diagnosis of CML is based on the morphological appearance of the bone marrow, peripheral blood cell morphology, and cytogenetic and molecular genetic studies. Cytochemistry and immunophenotyping are not particularly valuable in the diagnosis of CML in its chronic phase. This is the stage of the disease in which most CML patients first present.

- **Chronic-phase CML**—A significant hematologic finding in this phase of CML is a moderate to significant elevation of the neutrophil count, often with all stages of neutrophil maturation detectable in the peripheral blood smear. An increase in basophils is important to recognize, as modest basophilia is an early indication of CML. Approximately 50% of CML patients also have an elevation in their platelet count. The appearance of the bone marrow is hypercellular as the disease progresses in the chronic phase of CML, with an increase in the myeloid/erythroid ratio from 2:1-4:1 to 10:1-30:1. There is complete maturation of the granulocytes in CML.

- **Accelerated-phase CML**—There is no widely accepted definition for the accelerated phase of CML. The characteristic features of this phase of the disease include splenomegaly, an increase in the proportion of myeloblasts (10%-19%) and promyelocytes in the bone marrow over that found in the chronic phase, basophilia to >20% of the total WBC count, and anemia or thrombocytopenia.

- **CML in blast crisis**—By definition, when the percentage of blasts is 20% or more in the blood or bone marrow, blast transformation of CML has occurred. The blasts can be of either myeloid or lymphoid lineage; this determination is made by flow cytometry immunophenotyping. Approximately 70% of blast crises are myeloid. CML transforms into ALL in approximately 30% of cases of blast crisis. The immunophenotype is most commonly precursor B-cell ALL.

- **Cytogenetics**—The Philadelphia chromosome, t(9;22), is present in essentially 100% of CML cases; if the Philadelphia chromosome cannot be demonstrated by cytogenetics, FISH, or molecular studies, another diagnosis should be considered. Blast crisis is usually accompanied by additional cytogenetic abnormalities that appear with clonal evolution.

- **Molecular genetics**—The diagnosis of CML is still possible in cases that are Philadelphia chromosome negative by using FISH or reverse transcriptase PCR to detect the BCR–ABL1 fusion RNA. PCR can also be used to detect minimal residual disease in patients being treated for CML. Newer techniques are now available to quantify BCR–ABL1 RNA in the peripheral blood or bone marrow. These are being used to assess clinical responses to imatinib and to detect early evidence of imatinib resistance.

**Polycythemia Vera**

**Description**

Polycythemia vera is diagnosed by an increase in red cell mass with no apparent cause such as chronic oxygen deprivation (living at high altitude or heavy smoker). Transformation to acute myeloid leukemia is rare, but patients with polycythemia vera are at increased risk for the development of leukemia (see Chapter 10 for additional information on polycythemia vera).

**Diagnosis**

- **Cell counts and the peripheral blood smear**—By definition, the hemoglobin, hematocrit, and red cell count are all elevated. Patients often present with microcytosis and a normal hematocrit due to the iron deficiency that develops due to excessive red cell production. Because of this, these patients are sometimes initially thought to have thalassemia trait. The WBC count and platelet count are also often moderately elevated.

- **Bone marrow morphology**—The bone marrow can appear normal, but is often hypercellular with an increase in red cell precursors. With progressive disease, the bone marrow can become fibrotic.
• **Cytogenetics and molecular pathology**—Cytogenetic findings are usually normal. Definitive diagnosis is made by demonstrating a point mutation in the **JAK2** gene.

### Essential Thrombocythemia

**Description**

Essential thrombocythemia is diagnosed by an increase in platelet count with no other explanation. Platelet counts can frequently exceed 1 million/μL. Patients with essential thrombocythemia can manifest abnormal bleeding or blood clotting, although these complications are not very common. Transformation to acute myeloid leukemia is rare (see Chapter 11 for additional information on essential thrombocythemia).

**Diagnosis**

- **Cell counts and the peripheral blood smear**—Diagnosis is made by demonstrating a chronically elevated platelet count. The WBC count and hematocrit may also be moderately elevated.
- **Bone marrow morphology**—The bone marrow demonstrates an increase in megakaryocytes and an overall increase in cellularity. With progressive disease, the bone marrow can become fibrotic.
- **Cytogenetics and molecular pathology**—Cytogenetic findings are usually normal. Definitive diagnosis is made by demonstrating a point mutation in the **JAK2** gene, which occurs in about 50% of cases. Activating mutations in the thrombopoietin receptor gene, **MPL**, have also been described in 5% to 10% of cases.

### Primary Myelofibrosis

**Description**

Patients with primary myelofibrosis typically present with marked splenomegaly and some degree of hepatomegaly. The disease affects primarily older individuals. As the marrow becomes fibrotic and cytopenias in the peripheral blood develop, the complications associated with the cytopenias appear. Bleeding from low platelet counts and infections from low WBC counts may be lethal. A minority of patients with primary myelofibrosis (less than 10%) progress to acute leukemia, with a higher incidence in those who are treated with radioactive phosphorus or alkylating agents in the highly proliferative phase of their disease.

**Diagnosis**

- **Cell counts and the peripheral blood smear**—The peripheral blood frequently demonstrates a “leukoerythroblastic” picture, with leukocytosis, immature granulocytes including blasts, thrombocytosis, and the presence of immature erythroid cells including reticulocytes and nucleated red cells. The cell counts decline with disease progression.
- **Bone marrow morphology**—Initially, the bone marrow shows trilineage hypercellularity with megakaryocyte hyperplasia and reticulin fibrosis. With disease progression, there is replacement of the bone marrow by extensive fibrosis allowing little space for hematopoiesis.
- **Cytogenetics and molecular pathology**—Cytogenetic abnormalities are present in 30% to 60% of patients. Approximately 40% to 50% of patients with idiopathic myelofibrosis have the **JAK2 V617F** mutation.

### Myelodysplastic Syndromes

**Description**

Myelodysplastic syndromes include a group of bone marrow disorders with dysplastic (not normal, but not neoplastic) changes of the cells of the myeloid series. In myelodysplasia, the myeloblasts in the bone marrow must represent less than 20% of all nucleated marrow cells, because if there are 20% or more blasts, a diagnosis of acute myeloid leukemia is made. Because the myelodysplastic cells originate from an abnormal stem cell clone that is genetically unstable, there is a tendency for myelodysplasia to evolve into acute leukemia.
Myelodysplastic syndrome can occur as a primary disease or as a secondary disorder following exposure to chemotherapeutic agents or radiotherapy. Most cases of primary myelodysplastic syndrome are found in individuals over the age of 50 years. Many names have been applied to what is now called myelodysplastic syndrome, including preleukemia, refractory anemia (RA), and smoldering leukemia.

**Diagnosis**

Peripheral blood cytopenias are a hallmark of the myelodysplastic syndrome. As a result of ineffective hematopoiesis, myelodysplasia patients present with the complications of reduced blood cell counts in 1 or more cell lines. The complications include infections from low WBC counts, hemorrhage from low platelet counts, and weakness from anemia. In all forms of myelodysplastic syndrome, the bone marrow biopsy reveals hypercellularity.

A cytogenetic abnormality is found in 40% to 80% of the cases of primary myelodysplasia and 90% to 97% of patients with secondary myelodysplasia. These abnormalities may be useful as prognostic indicators. The most common changes are an interstitial deletion of the long arm of chromosome 5 (5q–) and deletions of chromosome 7 (–7, 7p–, or 7q–).

**WHO Classification of the Myelodysplastic Syndrome**

The myelodysplastic syndromes include a heterogeneous, but definable group of disorders. A brief description of each the disorders in the myelodysplastic syndrome is provided as follows:

- **RA**—This is defined as an anemia refractory to therapy. Dysplastic changes are only seen in the erythroid lineage. There are less than 5% bone marrow blasts, and ringed sideroblasts are less than 15% of the erythroid precursors.

- **Refractory anemia with ringed sideroblasts (RARS)**—This disorder is like RA except that 15% or more of the nucleated RBCs in the marrow are ringed sideroblasts. A ringed sideroblast, as noted in the section “Sideroblastic Anemia” (Chapter 10), is a cell in which at least 30% of the circumference of the nuclear membrane is covered by mitochondria containing iron granules.

- **Refractory cytopenias with multilineage dysplasia (RCMD)**—This disorder is like RA except that dysplasia is present in 2 or more lineages (lineages being myeloid, erythroid, and megakaryocytic). Auer rods (abnormal inclusions in myeloid blasts) are absent.

- **Refractory cytopenias with multilineage dysplasia and ringed sideroblasts (RCMD-RS)**—This disorder is like RCMD except that 15% or more of the nucleated RBCs in the marrow are ringed sideroblasts.

- **Refractory anemia with excess blasts-1 (RAEB-1)**—The major criterion for RAEB-1 is the presence of 5% to 9% of total nucleated cells in the bone marrow as blasts. There can be unilineage or multiligneage dysplasia. In addition, the percentage of WBC blasts in the peripheral blood must be less than 5% of nucleated cells. Auer rods are absent.

- **Refractory anemia with excess blasts-2 (RAEB-2)**—This disease is present if there are 10% to 19% blasts in the bone marrow, 5% to 19% blasts in the blood, or Auer rods in myeloblasts or other neutrophilic precursors. There can be unilineage or multiligneage dysplasia.

- **Myelodysplastic syndrome, unclassified (MDS-U)**—This disease is similar to RA except that dysplasia is present in 1 lineage other than the erythroid lineage. There are less than 5% blasts, and there are no Auer rods.

- **MDS associated with del(5q)**—Also known as “5q– syndrome,” there are normal to increased megakaryocytes with hypolobated nuclei, less than 5% blasts, no Auer rods, and the sole cytogenetic abnormality of del(5q).

**MYELODYSPLASTIC/MYELOPROLIFERATIVE NEOPLASMS**

The myelodysplastic/myeloproliferative neoplasm category was created for the 2008 WHO classification. This category is for clonal stem cell disorders that do not fit well into either the myelodysplastic or myeloproliferative disorders. The most common of these disorders is chronic myelomonocytic leukemia (CMML). Other rare disorders in this category include atypical chronic myeloid leukemia, juvenile myelomonocytic leukemia, and an unclassifiable category.
 CHAPTER 13  Diseases of White Blood Cells, Lymph Nodes, and Spleen  337

- **CMML**—This disorder is a chronic leukemia with dysplastic changes in the bone marrow that are indicative of an increased risk for transformation into acute myeloblastic leukemia. Patients with CMML have an absolute peripheral monocytosis greater than 1000 monocytes/μL, less than 20% blasts in the bone marrow, and dysplasia of 1 or more myeloid lineages.

**DISORDERS ASSOCIATED WITH IMPAIRED WBC FUNCTION**

WBCs must be present in appropriate numbers and also function normally. The disorders previously discussed in this chapter are associated with alterations in WBC number, and in some cases, impaired function as well. The 3 disorders presented in the following sections represent examples of WBC functional disorders with no alteration in WBC number. It is for this reason that they are also known as qualitative (as opposed to quantitative) WBC disorders. Many WBC qualitative disorders result in functional impairment and no increased risk for infections. However, other WBC functional abnormalities may be clinically significant and predispose to life-threatening infections.

**Chediak–Higashi Syndrome**

**Description**

This disorder is due to a mutation in a lysosomal trafficking regulator. The disorder is characterized by functional defects associated with azurophilic granules in the cells that have these granules. They are particularly prominent in neutrophils and melanocytes. Most patients with Chediak–Higashi syndrome are subject to recurrent infections. Chediak–Higashi patients also have partial albinism because they have defective melanosomes (which provide skin coloration). The platelets from these patients have a defect in storage granules. This platelet granule deficiency may produce a bleeding tendency because release of the granule contents is necessary for the platelets to aggregate and form platelet plugs.

**Diagnosis**

A personal and family history consistent with Chediak–Higashi syndrome, along with abnormal granules in all granulated hematopoietic cells and lymphocytes, strongly suggests the diagnosis.

**Chronic Granulomatous Disease**

**Description**

Chronic granulomatous disease (CGD) comprises a heterogeneous group of disorders in which recurrent bacterial infections can lead to an early death. The WBCs in CGD do not exhibit obvious morphological differences from normal WBCs. However, there are multiple biochemical defects in neutrophil function in CGD that limit their ability to produce peroxide and superoxides that destroy bacteria.

**Diagnosis**

Patients with CGD have a negative nitroblue tetrazolium (NBT) dye test. In this assay, a yellow dye is oxidized by the oxidative enzymes in the normal granules of neutrophils to form an insoluble blue-black compound detectable by light microscopy.

**Myeloperoxidase Deficiency**

**Description**

This disorder results from a defect in the pathway required for generation of free radicals, which are important in the destruction of invading microorganisms, similar to CGD. Although individuals with MPO deficiency may experience recurrent infections, the disorder is benign in most cases. The absence of MPO may be congenital or acquired.

**Diagnosis**

In patients with MPO deficiency, MPO staining of freshly prepared blood smears will produce only faint staining of the granules in neutrophils.

LEARNING OBJECTIVES
1. Learn the role of blood gases in the evaluation of the patient with pulmonary disease.
2. Understand how pleural fluid analysis is used in the diagnosis of pulmonary disorders.
3. Understand how bronchoalveolar lavage can aid in the diagnosis of respiratory disease.
4. Recognize the different laboratory tests used for assessing fetal lung maturity.

CHAPTER OUTLINE
Approach to the Patient With Pulmonary Disease 339
Blood Gases and Blood pH 342
Electrolytes and Anion Gap 342

Respiratory Distress Syndrome 347
Selected Laboratory Tests for Assessment of Fetal Lung Maturity 347
Lung Cancer 348

APPROACH TO THE PATIENT WITH PULMONARY DISEASE
Impaired exchange of gases is the unifying theme of respiratory disorders (Figure 14–1). Although they do not play a significant role in the diagnosis of specific pulmonary diseases, blood gas and electrolyte measurements (see Chapter 2 for blood gas determinations) are commonly used to assess the severity of different pulmonary abnormalities. The analysis of fluid located in the pleural space, which collects with certain abnormalities, constitutes another battery of tests often useful in the evaluation of pulmonary diseases. Careful analysis of respiratory secretions along with accompanying white blood cells, immune mediators, and foreign pathogens through bronchoalveolar lavage (BAL) aids in the diagnosis and management of lung disease. Infections in the respiratory tract are a major cause of pulmonary disorders. These are nearly always diagnosed using clinical laboratory tests (respiratory infections are discussed in Chapter 5). This chapter begins with a discussion of laboratory tests utilized in the diagnosis and monitoring of respiratory diseases and is followed by a section describing the most common lung diseases—asthma, respiratory distress syndrome (RDS) in adults and neonates, chronic obstructive pulmonary disease (COPD), and lung cancer.

Pulmonary disorders other than infections and tumors can be classified into 3 major groups. One group of disorders includes emphysema, bronchitis, asthma, and RDS. These are airway-based (bronchial) diseases. Inflammation or damage to the bronchi results in impaired
ventilation of alveoli (Figure 14–2). Another group of disorders affects the blood vessels, and, thereby, blood flow in the lung. Pulmonary vascular diseases are associated with reduced blood flow, resulting in nonuniform perfusion of the lungs (Figure 14–3). The third major group of pulmonary diseases is the interstitial lung disorders, which affect the tissue and space around the alveoli. These are a heterogeneous group of disorders associated with lung tissue damage due to scarring or inflammation. Damaged lung tissue is unable to fully expand, leading to thickening of the interface between alveoli and adjacent capillaries resulting in impaired diffusion of gases (Figure 14–4).

Clinical progression of pulmonary disease can lead to life-threatening respiratory failure. Acute RDS is a rapid-onset disease associated with severe breathing problems resulting from multiple insults to the lung (see more information below). It is distinct from "end-stage lung," which is the result of a chronic pulmonary disorder.
CHAPTER 14  The Respiratory System

FIGURE 14–3  Diagram of diseases with reduced blood flow, resulting in impaired perfusion of the lung.

FIGURE 14–4  Diagram of diseases with a thickened interface between alveoli and adjacent capillaries, resulting in impaired diffusion of gases.
Many disorders are associated with abnormalities in arterial blood $pO_2$, $pCO_2$, and pH. While these tests are not themselves diagnostic, they are valuable in assessment of the severity of respiratory diseases. The blood gas test panel includes:

- $pO_2$ or partial pressure of oxygen
- $pCO_2$ or partial pressure of carbon dioxide
- pH

The functional abnormalities most commonly detected with this battery of tests are:

- Low $pO_2$ (hypoxemia or low O$_2$ in blood, as opposed to hypoxia, which is reduced O$_2$ in tissues)
- High $pCO_2$ (hypercapnia)
- Low arterial blood pH with a primary respiratory cause (respiratory acidosis from an increased arterial $pCO_2$)
- Low arterial blood pH with a primary metabolic cause (metabolic acidosis, usually from increased acid production and/or impaired renal H$^+$ elimination, resulting in a decreased arterial HCO$_3^-$)
- High arterial blood pH with a primary respiratory cause (respiratory alkalosis from a decreased arterial $pCO_2$)
- High arterial blood pH with a primary metabolic cause (metabolic alkalosis from an increased arterial HCO$_3^-$)

The lungs respond within minutes to acid–base disturbances by 1) eliminating CO$_2$ (hyperventilation) to increase blood pH or 2) retaining CO$_2$ (hypoventilation) to decrease the pH.

The lungs respond within minutes to acid–base disturbances by 1) eliminating CO$_2$ (hyperventilation) to increase blood pH or 2) retaining CO$_2$ (hypoventilation) to decrease the pH. The kidney has the ability to 1) excrete H$^+$ and retain HCO$_3^-$ to increase pH or 2) retain H$^+$ and excrete HCO$_3^-$ to lower blood pH. However, renal compensation is slow and occurs over hours to days. Table 14–1 lists selected respiratory and nonrespiratory disorders associated with hypoxemia, and Table 14–2 presents selected respiratory and nonrespiratory disorders that can result in acid–base abnormalities.

**ELECTROLYTES AND ANION GAP**

Electrolytes are defined as either positively (cations) or negatively (anions) charged ions in the blood. Four freely circulating electrolytes are typically considered when evaluating acid–base disturbances (Na$^+$, K$^+$, Cl$^-$, and HCO$_3^-$). Blood gas and pH results are most important when investigating acid–base disruptions, and electrolytes play an important role in identifying the nature of the problem. Modern blood gas analyzers have expanded test menus to include electrolytes, facilitating their use in the evaluation of patients with suspected respiratory and/or metabolic disorders.

The anion gap refers to the difference between the major free cations (Na\(^+\) and K\(^+\)) and free anions (Cl\(^-\) and HCO\(_3\)^-). The calculation of the anion gap from measured electrolyte concentrations is critical for evaluation of acidosis. An elevated anion gap occurs when acid anions (such as lactate or ketones) are present. The amount of the increase in anion gap is equal to the amount of acid present because an increase in acid results in a proportional decrease in bicarbonate. Table 14–2 presents selected metabolic acidoses associated with an elevated anion gap.

## PLEURAL FLUID ANALYSIS

There are a number of disorders associated with the accumulation of fluid in the pleural space (Table 14–3). Pleural fluid can be collected by a pleural tap, also known as thoracentesis. An initial evaluation of color, physical characteristics, and odor of the fluid may help identify the
source. Next, the fluid is classified as an exudate or a transudate to limit the differential diagnosis and help identify the cause of its accumulation. Exudates and transudates are defined by the following criteria:

- **Exudate**—A filtrate of plasma out of the blood vessel, resulting from capillary damage or lymphatic obstruction (ie, significant loss of the blood/tissue barrier), with a relatively high concentration of protein (>3.0 g/dL) and:
  
  (a) \( \frac{\text{Pleural fluid total protein}}{\text{Serum total protein}} > 0.5 \)
  
  (b) Pleural fluid lactate dehydrogenase (LDH) > 20 IU/dL
  
  (c) \( \frac{\text{Pleural fluid LDH}}{\text{Serum LDH}} > 0.6 \)

- **Transudate**—An ultrafiltrate of plasma with a relatively low protein concentration (<3.0 g/dL) and values for \( \frac{\text{Pleural fluid total protein}}{\text{Serum total protein}} \), pleural fluid LDH, and \( \frac{\text{Pleural fluid LDH}}{\text{Serum LDH}} \) below what is required to define the fluid as an exudate.
  
  (a) \( \frac{\text{Pleural fluid total protein}}{\text{Serum total protein}} < 0.5 \)
  
  (b) \( \frac{\text{Pleural fluid LDH}}{\text{Serum LDH}} < 0.6 \)

Other laboratory testing on pleural fluid, while not diagnostic, may provide useful information in identifying the source of the fluid accumulation. These include total cell counts and differential, Gram stain, pH, glucose, lactate, amylase, triglycerides, and tumor markers. The section “Infections of the Lung and Pleurae” in Chapter 5 contains information on pleural fluid testing that is specific for infections.

**TABLE 14–3 Selected Disorders With Transudate or Exudate Formation**
**BRONCHOALVEOLAR LAVAGE FLUID ANALYSIS**

Analysis of the components of BAL fluid is an important diagnostic tool in assessment of numerous respiratory disorders. BAL analysis is most helpful when used in conjunction with clinical data and imaging results to aid in the diagnosis of pulmonary infections, particularly ventilator-acquired pneumonia, interstitial lung diseases, and lung cancers, and for monitoring of the allograft postlung transplant. Several aliquots of warmed saline are instilled in different areas of the lungs. At least 30% of the instilled fluid is carefully aspirated. BAL fluid is collected with the aid of a bronchoscope.

Bacterial cultures of the pooled fluid sample help identify an infectious cause of respiratory disease. Analysis of physical characteristics of the BAL collections also aids in the differentiation of disease. Bloody BAL fluid may indicate a diffuse alveolar hemorrhage, while cloudy BAL fluid suggests a diagnosis of pulmonary alveolar proteinosis. BAL fluid can also be processed to allow analysis of soluble biomarkers and cells. Studies of the BAL cell pellet include bacterial cultures, WBC count and differential, and Gram stain.

**LABORATORY TESTS USEFUL IN THE DIAGNOSIS OR MANAGEMENT OF PULMONARY DISEASES**

There are a number of pulmonary diseases for which laboratory tests (other than blood gases, BAL, and exudate/transudate determination discussed above) are useful in establishing a diagnosis. The most common of these are described below, while the rarer disorders are listed in Table 14–4 with their accompanying clinical laboratory test results. The infectious diseases of

</table>
the respiratory tract and pleurae are presented in Chapter 5. Pulmonary function tests provide information on airflow and lung volumes. Spirometry assesses pulmonary mechanics by quantitating the volume of air moved in different inspiratory and expiratory maneuvers, and the rate at which the air is moved. In addition, the uptake of a gas can be measured as an indicator of an impaired alveolar–capillary interface. These tests on airflow and gas exchange often do not identify a specific respiratory disorder, but they can suggest a category of diseases that may account for the airflow abnormalities. Because pulmonary function tests are performed outside the clinical laboratory, they are not discussed further in this text.

Radiologic studies, particularly plain chest radiographs, computed tomographic (CT) scans, magnetic resonance imaging (MRI), positron emission tomography (PET) scans, and nuclear medicine studies such as ventilation/perfusion scanning, play a prominent role in the diagnosis of pulmonary disorders.

**COMMON LUNG DISORDERS**

**Asthma**

Asthma is a chronic disease associated with reversible inflammation of the bronchial walls leading to narrowing of the airways. It is among the most common chronic diseases, and its prevalence is rising particularly in children. Acute onset of bronchial inflammation can lead to an asthma attack, with severe forms being life-threatening. While the exact cause of bronchial inflammation is unknown, there are numerous triggers including: environmental allergens (pollen, dust, and others), chemical allergens (cleaning agents, smoke, and others), exercise, stress, cold air, and medications.

**Diagnosis and Management**

The diagnosis of asthma is challenging because the clinical signs and symptoms overlap with many other respiratory diseases. Laboratory testing to rule out diseases such as cystic fibrosis (see Chapter 7) and infections (see Chapter 5) is important for the evaluation. Diagnosis begins with assessment of airway obstruction with spirometry and chest x-ray. The diagnostic evaluation for asthma must involve identification of inflammatory triggers. Identification of elevated concentrations of IgE in the plasma indicates a generalized allergic response. Antigen-specific IgE testing identifies immune responses to specific allergens and is useful in young children and patients with a contraindication to skin testing.

Initial diagnosis and monitoring of patients with an acute asthmatic reaction involves assessment of oxygenation for disease severity and pulmonary function. Evaluation of arterial blood gases also assesses oxygenation status. Evaluation of electrolytes, pH, and anion gap is helpful in evaluating acid–base status, pulmonary function, and tissue hypoxia (Table 14–2).

**Chronic Obstructive Pulmonary Disease**

Like asthma, COPD is a chronic inflammatory lung disease associated with airway obstruction. Inflammation leads to thickening of the airway wall and decreased airflow, as well as destruction of the alveoli and increased airspace. Patients with COPD have 2 main conditions, emphysema or chronic bronchitis. The biggest risk factor for both is cigarette smoking, followed by exposure to pollution. Currently, COPD is a major cause of morbidity and mortality worldwide, because it can lead to respiratory failure.

**Diagnosis and Monitoring**

A diagnosis of COPD is confirmed by the presence of clinical symptoms such as chronic cough, wheezing, and/or respiratory failure, combined with airflow obstruction determined by spirometry. Patients with COPD are followed by measuring arterial blood gases to assess oxygen status and monitor the benefit of long-term oxygen therapy. Exacerbations and increased disease severity are commonly monitored by measuring a complete blood count (CBC) to assess the level of inflammation, testing for respiratory infections (Chapter 5), and measurement of electrolytes, pH, and anion gap to assess acid–base status, pulmonary function, and tissue hypoxia (Table 14–2).
Respiratory Distress Syndrome

Acute Respiratory Distress Syndrome (ARDS)

ARDS is the rapid onset of respiratory failure due to systemic inflammation, trauma, or severe pulmonary infection in anyone over 1 year of age. It is associated with significant morbidity and mortality primarily due to oxygen deprivation and multisystem organ failure that results from pulmonary failure. A consensus group published the Berlin definition of ARDS as hypoxemia with bilateral lung infiltrates and/or respiratory failure within 1 week of a clinical insult, with new or worsening respiratory symptoms in the absence of cardiovascular insult or left pulmonary hypertension.

Diagnosis

The diagnosis of ARDS requires a careful clinical history to identify a recent clinical insult and/or the timing of new-onset respiratory symptoms. Chest x-ray or CT scan should be performed to visualize bilateral opacities. Cardiovascular ischemia and fluid overload should be ruled out by echocardiogram and/or cardiac biomarker analysis. Hypoxemia is classified by measuring arterial blood gasses and calculating the ratio of arterial partial pressure of oxygen to the fraction of inspired oxygen (Pao2/Fio2). The Berlin definition divides hypoxemia into mild (Pao2/Fio2 between 200 and 300 mm Hg), moderate (Pao2/Fio2 between 100 and 200 mm Hg), and severe (Pao2/Fio2 <100 mm Hg).

Neonatal Respiratory Distress Syndrome

RDS of the newborn is most commonly associated with incomplete development of the fetal lungs. The pulmonary system is one of the last to completely develop, and as a result, RDS is a common cause of morbidity and mortality in preterm infants. Symptoms of RDS begin within a few hours of birth due to a deficiency of pulmonary surfactant. Surfactant, a mixture of phospholipids and proteins, coats the alveolar surfaces and separates alveolar airspace from liquid-coated lung epithelial cells, preventing lung collapse during exhalation. RDS patients suffer both lung collapse and hyperextension of alveoli leading to fibrosis, or hyaline membrane disease. The alveoli in an RDS lung are perfused, but not ventilated, resulting in hypoxia, hypercapnia, and respiratory acidosis.

RDS can be addressed by preventing preterm births or by administration of corticosteroids at least 48 hours prior to a premature birth. Corticosteroids induce surfactant production, significantly reducing neonatal morbidity and mortality due to RDS. Assessment of FLM status is essential for clinical decisions for women with symptoms of preterm labor and for those whose labor is induced prior to 39 weeks gestation.

Selected Laboratory Tests for Assessment of Fetal Lung Maturity

FLM is most commonly assessed by testing the amount of surfactant in the amniotic fluid in women after 30 weeks gestation. The diagnostic test most commonly used to assess FLM is the lamellar body count (LBC) assay. Surfactant is packaged into storage granules called lamellar bodies that pass into amniotic fluid in the third trimester of pregnancy. LBCs >50,000/μL suggest maturity. Lamellar bodies are similar in size to platelets and can be counted on a standard whole blood counter.

Another method to assess fetal lung maturity is through calculation of the surfactant–albumin (S/A) ratio. The S/A ratio increases throughout gestation proportionally with lung maturity. Surfactant-based phospholipids, particularly lecithin (phosphatidylcholine) and phosphatidylglycerol (PG), also increase in the amniotic fluid during fetal lung maturation, while lipids not originating from the lung, such as sphingomyelin, remain fairly constant throughout gestation. Because of this, FLM can also be predicted by measuring the lecithin–sphingomyelin ratio. An L/S ratio > 2.0 indicates lung maturity. Qualitative detection of PG in amniotic fluid is a rapid and sensitive alternative for predicting FLM in late pregnancy. PG measurements are particularly useful in blood and meconium-contaminated amniotic fluid specimens as all other tests described above are affected by these contaminants.
Lung Cancer

Lung cancer, defined as any tumor of the respiratory epithelium or pneumocytes, is the leading cause of cancer-related mortality worldwide. The leading risk factor for lung cancer is cigarette smoking, accounting for up to 90% of cases. Exposure to environmental carcinogens, irradiation, and genetic disorders are also risk factors for developing lung cancer. There are 2 main types of lung cancers: small cell lung carcinoma (SCLC) and non-small cell lung carcinoma (NSCLC). Among NSCLCs the most common lung tumor type is adenocarcinoma. Most lung cancers are caused by acquired mutations, amplifications, or rearrangements in oncogenes including epidermal growth factor receptor (EGFR), fibroblast growth factor receptor type 1 (FGFR1), anaplastic lymphoma kinase (ALK), KRAS, NRAS, BRAF, HER2, PTEN, and MET, among others. Although some lung cancers are discovered in asymptomatic patients, the most common clinical signs include coughing up blood, wheezing, and shortness of breath.

Diagnosis and Monitoring

The diagnostic workup for lung cancer begins with discovery of a new pulmonary mass by chest x-ray, CT scan, or MRI. A definitive diagnosis of lung cancer and type is determined through histological and immunohistochemical analysis of tumor tissue. Molecular testing of advanced-stage adenocarcinoma type (NSCLC) is required to direct therapy. In particular, patients with EGFR mutations are more likely to respond to tyrosine kinase inhibitor (TKI) therapy and have longer progression-free survival. Patients with a KRAS gene mutation with or without an EGFR mutation do not respond to TKI therapy and should be treated alternatively. Advanced-stage non-small cell lung adenocarcinomas should also be tested for rearrangements in the ALK gene. About 5% to 10% of all NSCLC patients carry this rearrangement, which can be treated with an ALK inhibitor.

Prior to initiating therapy, baseline CBC and liver function panel should be measured to screen for metastases. Response to therapy and tumor recurrence can be monitored by performing regular chest x-rays and/or CT scans, as well as a CBC and liver function tests. Measurement of cytokeratin 19 fragments (CYFRA 21-1) in serum is useful for assessing prognosis in early and late stages, and in monitoring therapy in advanced stages of NSCLC. Serum neuron-specific enolase (NSE) may be useful in monitoring therapy and tumor recurrence in both NSCLC and SCLC.

CHAPTER 15

LEARNING OBJECTIVES
1. Understand the relative contributions of clinical laboratory tests and other diagnostic studies in the evaluation of the patient for a disorder of the gastrointestinal tract.
2. Learn the appropriate selection of diagnostic tests required to establish a diagnosis of ulcer disease from Helicobacter pylori infection.
3. Select the most appropriate tests for evaluation of suspected celiac disease, and learn the situations where results may be misleading.
4. Describe the recommended approaches to screening for colon cancer, and the benefits and limitations of laboratory tests for this purpose.

CHAPTER OUTLINE
Dyspepsia, Ulcer Disease, and H. pylori 351  
Colorectal Cancer 354  
Celiac Sprue 353

Most diseases of the gastrointestinal tract can be directly visualized by endoscopy or from a histopathologic review of a biopsy obtained during the endoscopic procedure. In addition, many gastrointestinal tract disorders can be identified with various imaging studies. This accessibility of lesions for direct examination and biopsy has limited the need for clinical laboratory tests in identifying most gastrointestinal disorders. However, because imaging studies are often expensive, and endoscopic procedures are both expensive and invasive, there is a clinical need for laboratory tests to aid in the diagnosis and management of persons with a number of gastrointestinal disorders. Infectious diseases involving the gastrointestinal tract are numerous, and are discussed in Chapter 5. The clinical laboratory plays an important role in identifying pathogenic microorganisms of the gastrointestinal tract.

The clinical laboratory also plays a role in the evaluation of dyspepsia (abdominal discomfort caused by acid), and/or ulcer disease, particularly that induced by Helicobacter pylori infection; in the recognition and monitoring of celiac sprue; and in the detection and genetic profiling of colon cancer. Laboratory tests for these disorders are presented in this chapter.

DYSPEPSIA, ULCER DISEASE, AND H. PYLORI

Description
According to the American Gastroenterological Association (AGA), dyspepsia is defined as chronic or recurrent pain or discomfort centered in the upper abdomen. Other conditions (particularly reflux of acid into the esophagus, referred to as gastroesophageal reflux disease [GERD]) can also cause abdominal discomfort, and it is often difficult to specifically characterize the type and location of discomfort. About 10% of those in the United States with upper abdominal
The major cause of peptic ulcer disease is infection with \( H. \) pylori. Not all patients with \( H. \) pylori infection develop ulcer disease, as many suffer from dyspepsia without ulcers.

Symptoms are found to have peptic ulcers, with a wide range between different countries. Other causes include gastritis related to use of nonsteroidal anti-inflammatory agents, and “functional dyspepsia,” in which no obvious pathology is present in the stomach.

The major cause of peptic ulcer disease is infection with \( H. \) pylori. The infection is most likely to occur in childhood, especially if the children are living in low socioeconomic conditions. In developed countries, \( H. \) pylori infection prevalence increases with age. Not all patients with \( H. \) pylori infection develop ulcer disease, as many suffer from dyspepsia without ulcers. The infection initially produces an acute gastritis that lasts 1 to 4 weeks. Once infected, however, chronic active gastritis occurs in the majority of individuals and may lead to more serious outcomes. Especially when infected in early childhood, individuals are at risk for the development of multifocal atrophic gastritis and over time, subsequently, have an increased risk for gastric adenocarcinoma.

**Diagnosis**

The evaluation of individuals with dyspepsia depends on age and the severity of symptoms. According to guidelines, direct visualization of the upper gastrointestinal tract by endoscopy is the preferred initial step in persons over age 55 years, or in younger patients who have a family history of gastric cancer or who also have more worrisome symptoms such as weight loss, difficulty swallowing food, recurrent vomiting, or gastrointestinal bleeding. In younger patients without these symptoms, the recommended approach is to test for the presence of active \( H. \) pylori infection and treat infected individuals. Those without evidence of infection are treated with drugs that inhibit acid production. Persons who do not respond to these treatments should then have an endoscopy.

Laboratory tests for \( H. \) pylori can be separated into those that identify exposure and those that detect active infection (Table 15–1). Because \( H. \) pylori is able to split urea (it is a urease-positive organism), its presence can be detected by ability of the individual to metabolize urea. The urea breath test (UBT) involves ingestion of a food product containing urea labeled with a small amount of radioactive carbon. If urease activity is present, the urea will be split into ammonia and carbon dioxide. The amount of radioactive carbon dioxide in the breath correlates with urease activity. The UBT has a high accuracy, and its performance is simple. Use of drugs that suppress acid production may cause falsely negative UBTs.

\( H. \) pylori has a unique surface antigen that can be detected in the stool of infected individuals, but not in those with inactive infection. Stool antigen testing with kits using monoclonal antibodies to the antigen is sensitive and specific. These kits have a high accuracy, for both initial diagnosis of \( H. \) pylori and posttreatment follow-up testing. Both the UBT and the stool antigen test can be used to evaluate the success of antibiotic treatment for \( H. \) pylori. Successful treatment should lead to loss of stool antigen (after several weeks) and the loss of urease activity in the stomach.

Serologic tests for IgG antibodies to \( H. \) pylori indicate past or current infection. They have a sensitivity and a specificity of only about 85% to 90%, and have largely been replaced by tests

</tbody>
</table>
that directly identify the organism. Serology is the only test not affected by reduction of bacterial load in the stomach, and, therefore, serologic testing for *H. pylori* is not subject to false-negative results when bacterial load reduction occurs. Unlike the stool antigen and urease tests, serologic tests remain positive for years after successful treatment, and because of that they are of no use to monitor the effects of treatment.

If endoscopy is performed, tests involving use of the biopsy material include a rapid urease test, histology, and culture with susceptibility testing. Susceptibility testing is increasingly important to detect resistance to clarithromycin because in resistant patients, the treatment success with clarithromycin is low. Molecular tests for *H. pylori* can also be used to detect the organism in gastric biopsies.

### CELIAC SPRUE

#### Description

Celiac disease is a systemic immune-mediated disorder. In genetically susceptible individuals, it is triggered by dietary gluten. Gluten is a complex of proteins that are found in wheat, rye, and barley. Gliadin is the water-soluble component in gluten. Celiac disease is extremely common, affecting 0.6% to 1% of the worldwide population. However, only a small percentage of cases of celiac disease are recognized. Its prevalence is higher in women, with increased incidence in individuals with an affected first-degree relative, or a relative with type 1 diabetes, Hashimoto thyroiditis, or other autoimmune disease. Importantly, genetic background greatly influences the predisposition to celiac disease. In 90% of patients with celiac disease, the HLA-DQ2 haplotype is expressed (which is present in only approximately one third of the general population). The HLA-DQ8 haplotype is expressed in 5% of the patients with celiac disease. This genetic predisposition occurs because the HLA-DQ2 and HLA-DQ8 haplotypes are expressed on the surface of antigen-presenting cells that bind activated (deamidated) gluten peptides. The HLA-DQ2 and HLA-DQ8 haplotypes are necessary, but their presence alone is not sufficient for the development of celiac disease. There are dozens of non-HLA genes that confer predisposition to celiac disease, and most of these are involved in the inflammatory and immune response.

Patients with celiac disease have chronic inflammation of the proximal small intestinal mucosa. The inflammation can heal when foods containing gluten are excluded from the diet. The inflammation returns if foods containing gluten are reintroduced. Gluten-associated storage proteins derived from wheat, barley, and rye undergo partial digestion in the upper gastrointestinal tract. The partial digestion results in the generation of derivatives of the native peptides, and these specific peptides can elicit an immune response. The enzyme transglutaminase deamidates glutamine to negatively charged glutamic acid residues in gliadin peptides, which then stimulate the immune response and the subsequent intestinal injury.

Mildly affected individuals may have symptoms such as bloating, irregular bowel movements, and cramps (often referred to as irritable bowel syndrome). Celiac disease patients may present with malabsorption of certain essential nutrients, including iron. About 5% of iron deficiency in adults is thought to be due to celiac disease. Malabsorption of folate and vitamin D, which may present clinically as osteoporosis, can also occur.

#### Diagnosis

Laboratory testing for celiac disease is summarized in Table 15–2.

#### Serologic Tests

A serologic test for IgA anti-tissue transglutaminase (tTG) antibodies is recommended as the initial testing for individuals who do not have a concomitant IgA deficiency. This is the most widely used test and has a sensitivity and a specificity over 98%, especially now that human tTG is used in the test as a reagent. As many as 3% of those with classic celiac disease have a deficiency of IgA, which results in a falsely negative test result. In a person with a high suspicion for celiac disease and a negative anti-tTG result, measurement of IgA to determine if the patient is IgA deficient is recommended. In persons with IgA deficiency, IgG, instead of IgA, anti-tTG antibodies can be measured. Another alternative for IgA-deficient patients is the measurement of the IgG
deamidated gliadin peptide antibodies. Tests for antibodies to deamidated gliadin peptides are less sensitive and less specific in adults for diagnosis of celiac disease, but they are more sensitive than anti-tTG assays in children. Antibody tests to gliadin are less likely to be positive in milder cases, and, like the other serologic tests, often become negative when gluten is eliminated from the diet. Some patients may be monitored with antibody levels to gliadin to monitor compliance with treatment.

The endomysium is a connective tissue that ensheaths each individual muscle fiber. Antien-
donysial antibodies are present in patients with celiac disease. They are useful in the diagnosis of the disease, but do not cause any direct symptoms associated with muscles. The presence of antienendomysial antibodies is nearly 100% specific for active celiac disease, but these antibodies are found in other autoimmune diseases, and for that reason this antibody measurement should be used as a confirmatory test for borderline cases initially tested with an anti-tTG antibody assay. Patients with celiac disease can be differentiated from patients with simple gluten sensitiv-
ity and patients with wheat allergy because the antibodies found in celiac disease are absent in those with gluten sensitivity or wheat allergy. In addition, for celiac disease, the interval between exposure to gluten and onset of symptoms is weeks to years. This is in contrast to simple gluten sensitivity where the interval between exposure and onset of symptoms is hours to days, and wheat allergy where the interval is minutes to hours.

Biopsy
The diagnosis of celiac sprue currently requires endoscopy with biopsy of the duodenum. In severe cases, there is atrophy of villi and flattening of the mucosa, but milder cases may show only lymphocytes infiltrating the mucosa. In children, recent guidelines suggest that a biopsy may not be required if there are typical symptoms and a high titer of anti-tTG antibodies, along with HLA-DQ2 and/or HLA-DQ8 genotypes.

COLORECTAL CANCER

**Description**
Because colorectal cancer is the second most common cause of cancer death in both men and women, and because early detection is associated with better survival, there is widespread accep-
tance of the benefits of screening those over age 50 years for colorectal cancer (see Table 15–3). Screening may also detect adenomas of the colon, which have been recognized to be the precursors of most cases of invasive cancer. The most sensitive screening test for colorectal cancer is colonoscopy.
Diagnosis—Screening for Colorectal Cancer

Because colonoscopy is an invasive and expensive procedure with risks involved, other approaches to screening are also approved. These include fecal occult blood testing (FOBT) and fecal immunochemical testing (FIT). Both of these tests involve testing stool for the presence of blood. The FOBT uses guaiac, a reagent that reacts with hemoglobin and a number of other substances to produce a blue color when blood is present. Guaiac tests react with animal hemoglobin as well, so restrictions on meat intake are required for several days before samples are collected. Iron and certain plants also can cause a blue color with guaiac, and their intake should also be restricted. The testing is done by having an individual take 2 samples from 3 consecutive bowel movements, and smearing these small samples onto cards that are sent to a site where they can be tested. This test has a poor sensitivity for detecting colorectal cancer.

The fecal immunochemical test (FIT), using antibodies to human hemoglobin, is slightly more expensive, but does not require dietary restriction before testing. Both types of tests for hemoglobin are approved in commonly used guidelines. However, the FIT has a much higher sensitivity than the FOBT for detection of colorectal cancer and also for detecting advanced adenomas that can develop into cancer.

Colonoscopy needs to be repeated infrequently, every 10 years if no adenomas are found starting at age 50 in persons who are not considered to be at high risk for colorectal cancer. Colonoscopy should be more frequently performed for those with adenomas or with a strong family history of colon cancer. FIT or FOBT should be performed every year. Any abnormal results should be followed up by colonoscopy.

Colorectal cancer, like most cancers, is associated with a number of mutations in genes related to cell growth and regulation. It is possible to identify DNA from shed cells in stool. Some studies have shown that testing for multiple mutations in genes associated with colon cancer has a higher sensitivity than FOBT, although not as high as colonoscopy. The DNA test requires special handling, with collection of stool into a container that has been stored frozen, and rapid delivery after collection to the testing laboratory. It is similar in expense to colonoscopy at present. Laboratory testing to screen patients for colorectal cancer is summarized in Table 15–3.

Diagnosis—Genetic Profiling for Colorectal Cancer

Histologically, the most common subtype of colorectal cancer is adenocarcinoma. Colorectal adenocarcinomas can arise upon acquisition of a variety of mutations over many years. These genetic alterations can lead to the conversion of normal colonic epithelium first to adenoma, and then to carcinoma, and this carcinoma frequently metastasizes. There has been increasing recognition that some of the genetic alterations can be used as prognostic markers for outcome and can be useful in the selection of specific therapies for the patient with colorectal cancer. As an example,
1 genetic profile for colon cancer involves the analysis of 63 mutations in the following 7 genes—KRAS, BRAF, PIK3CA, AKT1, SMAD4, PTEN, and NRAS.

LEARNING OBJECTIVES

1. Identify the laboratory tests useful in the evaluation of liver function, and the pathophysiology that results in the generation of these abnormal test results.
2. Understand the clinical laboratory evaluation of the patient for viral hepatitis.
3. Associate specific disorders of the liver with the laboratory test results expected for those clinical diagnoses.

CHAPTER OUTLINE

Introduction 357
Plasma Membrane Integrity and Disorders Predominantly Associated With Elevated Concentrations of Liver-derived Enzymes in the Blood 358
Detoxifying and Excretory Functions of the Hepatobiliary System and Disorders Associated Predominantly With an Elevated Bilirubin Concentration 361

Approach to the Patient With Liver Disease 369

INTRODUCTION

Laboratory evaluation of the hepatobiliary system centers on measurements of: 1) hepatocyte plasma membrane integrity, 2) measurements of the detoxifying and excretory functions of the hepatobiliary system, and 3) measurements of the synthetic capacity of hepatocytes.
PLASMA MEMBRANE INTEGRITY AND DISORDERS PREDOMINANTLY ASSOCIATED WITH ELEVATED CONCENTRATIONS OF LIVER-DERIVED ENZYMES IN THE BLOOD

With hepatocyte or biliary tract disease, many cellular enzymes are released that enter the circulation. Enzymes indicative of hepatocyte disease are alanine aminotransferase (ALT) and aspartate aminotransferase (AST). Alkaline phosphatase (ALP) elevations relate to biliary tract disease (Table 16–1).

Enzyme concentrations are usually measured by determining the enzyme activity in serum or plasma. Such measurements are reported as units per liter or international units per liter, where the unit is an activity measurement (eg, the rate of appearance of product or disappearance of substrate per unit time).

Normally, the healthy plasma membrane and various organelles contain (eg, “hold”) enzymes within the cell. An elevated enzyme level in the blood suggests organ dysfunction because of a functional or anatomic disruption in the plasma membrane. One way to assess the degree of elevation of an enzyme is to calculate the ratio of the patient’s enzyme concentration relative to the upper limit of the reference interval. For example, if the upper limit of the reference interval for ALT were 40 U/L and the patient’s ALT was 120 U/L, the patient’s ALT would be said to be “3 times above the upper limit of normal.”

While not specific for hepatocytes, elevations of ALT and AST are characteristic of hepatocellular disease. The major sources of ALT include the liver and the kidney. Lesser amounts are released from skeletal and cardiac muscle. AST is also found in these organs. ALT is exclusively localized in the cell cytoplasm. AST is located in the cytoplasm and mitochondria. However, AST derived from the cytoplasm and mitochondria cannot be distinguished through clinical laboratory testing. ALT is more specific for the liver than AST. Usually ALT and AST rise in tandem in liver disease states. Although there is more AST in hepatocytes than ALT, ALT is metabolized more slowly than AST accounting for similar concentrations of these enzymes in the patient’s plasma as released from the liver.

One condition where AST is often elevated to a greater extent than ALT is in chronic liver disease resulting from chronic alcohol abuse. People with alcoholism are not uncommonly pyridoxine deficient because of deficient dietary intake of this vitamin. While both AST and ALT are pyridoxine dependent for their biochemical activity, ALT is more dependent on pyridoxine than AST. Thus, a rise in the measured ALT may not be as great as the rise in measured AST because ALT activity suffers more from pyridoxine deficiency than does AST. If the AST to ALT ratio is greater than 2 in the setting of chronic liver disease, alcoholic liver disease is strongly suggested. With cirrhosis of any etiology, enzyme elevations may be modest, or their concentrations may be surprisingly normal, reflecting a marked loss in hepatocyte mass and, thereby, a loss of enzymes within the liver.

</tbody>
</table>
In the past, lactate dehydrogenase (LD) was also regularly employed as a marker of hepatocellular disease. (Note: The older abbreviation for lactate dehydrogenase was “LDH.”) However, LD is not favored for routine evaluation of the hepatocyte integrity currently because LD is released with injury of many different tissues. Both ALT and AST are more specific for liver disease or injury than LD.

Measurement of LD isoenzymes is possible, but there are more informative tests that can be ordered to evaluate specific organ dysfunction. LD is composed of 4 subunits. The subunits are H (for heart) and M (for muscle). If required, LD isoenzymes can be determined by electrophoresis. The subunit composition and major sources of each of the 5 isoenzymes are listed in Table 16–2. The LD4 isoenzyme provides no specific clinically useful information.

If the total LD is increased in a patient with suspected liver disease, and the patient lacks skeletal muscle and prostate disease, it is expected that LD5 will be elevated because of the liver disease. The enzyme marker of choice for the evaluation of skeletal muscle injury or disease is creatine kinase (CK). If the CK is normal in the setting of an elevated LD5, skeletal muscle is not likely to be the source of the elevated LD5.

Biliary tract disease produces relatively greater increases in ALP than increases in ALT, AST, or LD. ALP is associated with the plasma membrane of hepatocytes adjacent to the biliary canaliculus. Obstruction or inflammation of the biliary tract results in an increased concentration of the ALP in the circulation. Similar to ALT and AST, ALP is not specific for biliary tract disease. ALP is released by osteoblasts, the ileum, and the placenta. ALP is elevated: 1) in children 2- to 3-fold over adults because the child's skeleton is growing, 2) with bone disease involving osteoblasts (eg, metastatic cancer or following a fracture), 3) in hyperparathyroidism where parathyroid hormone stimulates osteoblasts through a series of steps that enhances bone resorption (eg, parathyroid adenoma, hyperplasia, or secondary hyperparathyroidism from vitamin D deficiency or renal disease), 4) in cases of ileal disease, and 5) during the third trimester of pregnancy because the placental isoenzyme is elevated.

When the etiology of the elevated ALP is unclear, in the past ALP isoenzymes were determined. However, there are many technical problems with these assays. Today it has proven more pragmatic to measure other biliary tract enzyme markers such as gamma-glutamyl transpeptidase (GGT; aka gamma-glutamyltransferase) or 5'-nucleotidase (5'-NT). The proximal convoluted tubule of the kidney, the liver, the pancreas, and the intestine are sources of GGT, in decreasing order of tissue concentration. Within the cell, GGT is located in microsomes and along the biliary tract plasma membrane, GGT is more commonly measured than 5'-NT because GGT testing is widely available on a variety of laboratory instruments. GGT is typically not elevated with bone disease. Combined elevations of ALP and GGT are compatible with biliary tract disease. However, if the ALP is elevated to a far greater extent than the GGT (or the GGT is normal), ALP sources other than the biliary tract, such as bone, must be investigated. GGT elevations occur in response to alcohol use and anticonvulsants, as GGT is induced by such agents. While there is no specific biochemical test to prove that a patient suffers from alcohol abuse, carbohydrate-deficient transferrin levels can be elevated in patients suffering from alcoholism.

Using the information presented, one can interpret of liver enzyme elevations in patients with suspected liver disease. If the relative increase in ALT or AST over the upper limit of
normal exceeds the relative increase in ALP over the upper limit of normal, the liver disease is predominantly hepatocellular as opposed to biliary tract.

Causes of acute hepatocellular disease include (Table 16–3) viral hepatitis (eg, hepatitis A, B, or C), alcoholic hepatitis, toxic injury (eg, acetaminophen poisoning), and ischemic injury (eg, hypotension). In cases of ischemic injury or toxic injury following an acute toxic ingestion, the ALT and AST levels can rise and peak within 24 hours of the precipitating event. Less common causes of acute liver disease include hepatitis due to hepatitis D, hepatitis E, cytomegalovirus (CMV), Epstein–Barr virus (EBV), and herpes virus; autoimmune hepatitis (marked by positivity for antinuclear antibodies [ANA], smooth muscle autoantibodies [ASMA], and/or liver–kidney microsome autoantibodies [anti-LKM1 autoantibodies] and negative antimitochondrial autoantibodies [AMA]); Wilson disease; and liver disease of pregnancy. Three forms of liver disease in pregnancy include fatty liver, intrahepatic cholestasis, and hepatic dysfunction associated with toxemia (eg, part of the HELLP syndrome: hemolysis, elevated LFTs [eg, enzymes], and low platelets).

Chronic hepatocellular disease is diagnosed when liver disease is present for more than 6 months (Table 16–3). Causes of chronic hepatocellular disease include hepatitis B or C, drug toxicity (eg, statins, sulfonamides, or INH), alcoholic liver disease, nonalcoholic fatty liver (NAFL), inborn errors (include hemochromatosis, alpha-1 antitrypsin deficiency, Wilson disease, glycogen storage disease, and Gaucher disease); and autoimmune hepatitis.

If the relative increase in ALP over the upper limit of normal exceeds the relative increase in ALT or AST over the upper limit of normal, the liver disease predominantly involves the biliary tract (Table 16–4). A major manifestation of obstructive biliary tract disease is an elevated bilirubin concentration. Clinical jaundice results when the total bilirubin exceeds 2 to 3 mg/dL.
DETOXIFYING AND EXCRETORY FUNCTIONS OF THE HEPATOBILIARY SYSTEM AND DISORDERS ASSOCIATED PREDOMINANTLY WITH AN ELEVATED BILIRUBIN CONCENTRATION

A major biochemical responsibility of the liver is to metabolize toxins, drugs, and biologic end products and excrete many of the resulting metabolites into the bile. The easiest endogenous end product to assess is the bilirubin concentration in the plasma. Bilirubin is predominantly derived from hemoglobin in the normal turnover of red blood cells, and to a lesser extent, from myoglobin in muscle. Red blood cells normally circulate for approximately 120 days. Red blood cell senescence and destruction in monocytes/macrophages, primarily in the spleen, releases hemoglobin from red blood cells. Within the phagocyte, hemoglobin is then metabolized to biliverdin and finally to bilirubin. The bilirubin then enters the circulation. This form of bilirubin (ie, “unconjugated” bilirubin) is relatively insoluble in water and is transported to the hepatocyte bound to albumin. It is not excreted in the urine. Unconjugated bilirubin is normally taken up into hepatocytes via a transport system. Inside the hepatocyte via the action of UDP-glucuronyl transferase, either 1 or 2 glucuronide molecules are conjugated to bilirubin, making the bilirubin water soluble. Conjugated bilirubin is bilirubin monoglucuronide or bilirubin diglucuronide. Conjugated bilirubin is then transported across the plasma membrane into the bile canaliculi along with bile via multiple drug resistance (MDR) transporter proteins. If the concentration of either conjugated or unconjugated bilirubin rises pathologically, the skin and sclera can develop a yellowish color, termed jaundice. With marked elevations in bilirubin, patients may acquire a green hue. Pathologic elevations in water-soluble bilirubin (eg, conjugated bilirubin) can lead to bilirubin excretion in the urine (bilirubinuria), causing the urine to develop a yellow-brown or green-brown color.

Bilirubin is most often measured by reacting the patient’s serum or plasma with Ehrlich reagent that includes a diazo compound. The conjugated fraction reacts most rapidly with the reagent because the conjugated fraction is water soluble. This is termed “direct acting,” or more commonly, “direct” bilirubin. To measure total bilirubin, solubilizing agents must be added to the serum or plasma to enhance the reaction of the water-insoluble bilirubin (ie, unconjugated bilirubin) with the reagents. Caffeine or benzoate can be used for this purpose. Because only direct and total bilirubin can be measured, indirect (unconjugated bilirubin) is calculated as the difference between the total and the direct bilirubin. While the terms “direct” and “conjugated” are used synonymously just as the terms “indirect” and “unconjugated” bilirubin are used synonymously, it should be noted that these are approximations. In fact, direct bilirubin measures 70% to 90% of the conjugated bilirubin, delta bilirubin (biliprotein, see below), and 5% to 10% of the unconjugated bilirubin.

If the concentration of either conjugated or unconjugated bilirubin rises pathologically, the skin and sclera can develop a yellowish color, termed jaundice.

*The relative elevation in ALP exceeds the relative elevations in ALT and AST.*
While the chemical measurement of bilirubin using Ehrlich reagent is the scheme used in the majority of automated chemistry analyzers, it is necessary to review how bilirubin is measured using dry slide technology that was originally developed by Kodak. The unique feature of dry slide technology (as provided in the Vitros series of analyzers) is the ability to spectrophotometrically determine the unconjugated (BU: bilirubin unconjugated) and conjugated bilirubin (BC: bilirubin conjugated) fractions. The difference between the sum of the BU and BC and the total bilirubin measured via the Ehrlich reaction is the delta bilirubin (aka biliprotein). Delta bilirubin is bilirubin that is covalently bound to albumin. Elevated levels of delta bilirubin are consistent with chronic elevations in bilirubin. However, only 1 analytical system is able to estimate delta bilirubin (ie, dry slide technology) and the calculation of the delta bilirubin has not yet been shown to be clinically informative.

In most cases involving hepatocellular dysfunction (notably, acute viral hepatitis), the major relative increase in bilirubin is an increased conjugated bilirubin fraction because transport of conjugated bilirubin into the bile canaliculus is typically the rate-limiting step in bilirubin excretion. With the failure of transport of conjugated bilirubin into the bile canaliculus, the conjugated bilirubin refuxes into the systemic circulation. However, with severe hepatocellular dysfunction, as might occur in cases of end-stage liver disease, there can be defective conjugation in addition to defective canalicular transport.

It is useful to classify hyperbilirubinemia as predominantly unconjugated or conjugated. This assists in the development of an appropriate differential diagnosis. If the ratio of the conjugated bilirubin to total bilirubin is less than 0.4, an unconjugated hyperbilirubinemia is present. When the ratio of conjugated to total bilirubin is 0.4 or greater, predominantly a conjugated hyperbilirubinemia is present. In neonates, the cutoff ratio is near 0.2 because unconjugated bilirubin is normally much higher in neonates than in children or adults.

Causes of unconjugated hyperbilirubinemia involve 3 basic mechanisms: 1) increased red blood cell destruction (“prehepatic”), 2) defects in the transport of unconjugated bilirubin into the hepatocyte, and 3) defective conjugation. Major causes of increased red blood cell destruction include intramarrow hemolysis (eg, vitamin B\textsubscript{12} deficiency causing ineffective erythropoiesis), intravascular or extravascular hemolysis (eg, microangiopathic hemolytic anemia, hemolysis from an artificial heart valve, and autoimmune hemolytic anemia [“warm,” IgG-mediated and “cold,” IgM-mediated]), intrinsic membrane defects in red blood cells (eg, congenital spherocytosis or elliptocytosis), red blood cell enzyme defects (eg, glucose-6-phosphate dehydrogenase [G6PD] deficiency or pyruvate kinase [PK] deficiency), and hemoglobinopathies (eg, sickle cell anemia) (Table 16–5).

DIC, disseminated intravascular coagulation; TTP, thrombotic thrombocytopenic purpura; HUS, hemolytic uremic syndrome; G6PD, glucose-6-phosphate dehydrogenase.
A variety of nonhemolytic conditions can cause an unconjugated hyperbilirubinemia (Table 16–6). Gilbert syndrome is a benign autosomal dominant disorder in which there is a mild defect in the uptake of bilirubin by the hepatocyte, combined with a mild defect in conjugation. Clinical jaundice does not usually occur in the absence of concurrent disease (eg, gastroenteritis or other mild conditions). Liver enzyme concentrations and hepatic synthetic ability are normal, and, therefore, Gilbert syndrome is best considered a variation of normal and not a disease. On the other hand, a congenital deficiency of UDP-glucuronyl transferase is a serious condition. Absolute deficiency of UDP-glucuronyl transferase, which results in Crigler–Najjar syndrome type I, will cause marked elevations in unconjugated bilirubin that will result in kernicterus in infants if untreated. The treatment of this disease is liver transplantation. A milder deficiency of UDP-glucuronyl transferase, Crigler–Najjar syndrome type II, may be treated with barbiturates to stimulate production of the deficient enzyme. A transient, mild, self-limited deficiency of UDP-glucuronyl transferase activity is common in newborns (eg, neonatal jaundice; aka icterus neonatorum). However, if the bilirubin rises above ∼5 to 10 mg/dL in a neonate, phototherapy is used to reduce the bilirubin concentration. One recommendation is to begin phototherapy when the bilirubin is 5 times the birth weight. An unconjugated, transient hyperbilirubinemia occurs in 2% to 10% of breastfed infants (ie, breast milk jaundice). In these infants, it is believed that a constituent in the breast milk interferes with bilirubin conjugation, thereby elevating unconjugated bilirubin.

The etiologies of conjugated hyperbilirubinemia involve 2 basic mechanisms: 1) hepatocellular disorders with decreased transport of conjugated bilirubin into the bile canaliculus (Table 16–3) or 2) biliary tract obstruction (Table 16–4). Moderate-to-severe acute or chronic hepatocellular disease can produce a conjugated hyperbilirubinemia. Hepatocellular disorders associated with impaired plasma membrane integrity and release of enzymes into the circulation were discussed earlier.

Of note are 2 disorders in which there is a conjugated hyperbilirubinemia with otherwise normal hepatic function. These are Dubin–Johnson syndrome and Rotor syndrome. Dubin–Johnson syndrome results from dysfunction of the multidrug resistance protein 2 (MRP2) that is a canalicular multispecific organic anion transporter (cMOAT), the gene product of ABCC2. The liver is stained black in this condition. Rotor syndrome is a consequence of decreased hepatic glutathione-S-transferase levels (hGSTA1-1). In the absence of a liver biopsy, Dubin–Johnson and Rotor syndromes have been distinguished by urine testing for coproporphyrins and coproporphyrin I that are abnormal in Dubin–Johnson syndrome. DNA testing is used progressively more often to distinguish these disorders.

Biliary tract obstruction can be intrahepatic or extrahepatic. The most common cause of extrahepatic biliary tract obstruction after the neonatal period is cholelithiasis.
Compared with the timing of elevations in the enzymes of hepatic origin following a liver insult, elevations in bilirubin occur later. Also, while the degree of increase in the concentration of the hepatic enzymes correlates poorly with the degree of liver injury or disease, greater elevations in the level of conjugated bilirubin do correlate with more severe degrees of liver disease. In end-stage liver disease as found in alcoholic cirrhosis, for example, ALT and AST may only be modestly elevated, yet the patient may exhibit intense jaundice. In such cases, portal hypertension is frequent with ascites and esophageal varices, hemorrhoids, and splenomegaly.

SYNTHETIC FUNCTION OF THE LIVER AND DISORDERS ASSOCIATED WITH LOW CIRCULATING CONCENTRATIONS OF ALBUMIN, TRANSTHYRETIN, RETINOL-BINDING PROTEIN, AND COAGULATION FACTORS

Excluding immunoglobulins, which are the products of B cells and plasma cells, the liver is the major source of circulating proteins. On a strictly quantitative basis, albumin is a better measure of synthetic ability than total protein. A substantial degree of hypoalbuminemia can exist, yet the total protein may be normal or elevated because of a coexistent polyclonal or monoclonal hypergammaglobulinemia. Besides liver disease, there are several other causes of hypoalbuminemia including malnutrition and malabsorption (insufficient nutritional substrate for albumin synthesis), acute inflammation where protein synthesis is redirected from albumin to acute-phase reactants (eg, complement proteins, C-reactive protein, mannose-binding lectin, and serum amyloid A; Table 16–7), and protein loss from nephrosis or protein-losing enteropathy.

In nutritionally deficient patients, nutritional replenishment can be assessed by measurement of retinol-binding protein, or, more commonly, transthyretin (thyroxine-binding prealbumin). While transthyretin is commonly referred to as “prealbumin,” strictly speaking, prealbumin is a region on a serum protein electrophoresis gel that precedes albumin. In contrast to albumin, transthyretin and retinol-binding protein are not usually measured as indices of hepatic dysfunction.

Assessment of clotting factor proteins through measurement of clotting factor activity tests (such as the prothrombin time [PT]) is a useful assessment of liver synthetic function. An increase in the PT, or the international normalized ratio (INR) derived from it, can be a sign of serious liver dysfunction. Because the half-life of many clotting factors is much shorter than the half-life of albumin, in cases of acute liver dysfunction, measurement of the PT can provide a more sensitive index of decreased liver protein synthesis than albumin. The PT involves factors VII, X, V, II (prothrombin), and I (fibrinogen). The half-life of factor VII is the shortest of any clotting factor and is only 4 to 5 hours.

Despite the synthetic information provided by a prolonged PT, the severity of the coagulopathy may not correlate closely with the degree of prolongation of the PT because anticoagulant factor production may also be reduced with severe liver disease (eg, reduced synthesis of antithrombin, protein S, and protein C). This means that the degree of bleeding may be less than expected based on the degree of prolongation of the PT.

Moderate-to-serious liver disease can lead to bleeding for many reasons. Vitamin K malabsorption, decreased clotting factor concentrations and activity (the vitamin-K-dependent factors are II, VII, IX, and X), and impaired clearance of fibrin-split products can all occur with liver dysfunction. Fragments of fibrin can interfere with the formation of a stable and firm clot. With cirrhosis, increased portal pressure can produce esophageal varices that are easily traumatized, resulting in bleeding. Increased portal pressure can produce splenomegaly, leading to platelet sequestration. Thrombocytopenia is not uncommon in severe liver disease. Thrombopoietin is produced by the liver.

THE DIAGNOSIS OF VIRAL HEPATITIS

Hepatitis serologic tests are used to diagnose viral hepatitis or recognize past exposure or immunization to a virus that can cause hepatitis. The hepatitis A virus (HAV) is an RNA virus that commonly causes acute hepatitis and is transmitted through the fecal–oral route. Fulminant hepatic necrosis is possible but very rare, and chronic liver disease does not result from HAV infection. Total antibody to HAV can be measured, and when it is positive, there are elevations of IgM and/or IgG antibodies to HAV. Positivity for the IgM antibody to HAV indicates acute or recent infection. Positivity for the HAV total antibody test does not distinguish patients with acute infection from those with a past infection who have recovered or from immunized individuals (Table 16–8).

Acute hepatitis B virus (HBV; a DNA virus) infection is serologically first noted by the appearance of HBV surface antigen (HBsAg). This is followed by HBV e antigen (HBeAg) and then HBV IgM core antibody (HBc IgM antibody). During recovery, the HBsAg and HBeAg disappear from the circulation, HBc IgM antibody converts to negative, and HBc total antibody appears, followed by HBe antibody (HBeAb), and then HBs antibody (HBsAb).

In cases of chronic HBV infection, HBsAg remains positive. HBeAg positivity is variable, and its presence indicates increased infectivity. HBeAb positivity is also highly variable. Immunization results in positivity for HBsAb, but not HBcAb, as the immunogen used for immunization is recombinant-DNA derived HBsAg.

Hepatitis C virus (HCV; an RNA virus) is the most common viral cause of chronic hepatitis with 40% to 80% of acute infections leading to chronic hepatitis (eg, hepatic disease exceeding 6 months duration). A positive HCV antibody test does not distinguish acute from chronic infection, and it does not distinguish patients with active infection from those who have recovered. HCV antibody positivity previously could be confirmed by the recombinant immunoblot assay (RIBA), but RIBA testing is no longer available. However, RIBA testing has the same diagnostic limitations as the HCV antibody testing. Evidence of active HCV infection is provided by elevations in transaminases, liver biopsy, or detection of HCV RNA by nucleic acid testing (eg, RT-PCR, bDNA, or transcription-mediated amplification testing). Normal levels of AST and ALT do not exclude chronic HCV infection (see Chapter 2 for illustrations of molecular methods).

Hepatitis D virus (HDV; a DNA virus) is a defective virus that requires coinfection of the host with HBV for the expression of HDV hepatitis. HBV and HDV infection can occur concurrently or HDV infection can be superimposed on chronic HBV infection. HDV uses the surface antigen of HBV to form a virion. IgM antibody to HDV indicates acute infection. HDV total antibody has...
the same diagnostic limitations as HCV antibody; notably, active infection is not differentiated from recovery, and acute and chronic infections are not distinguished.

**SELECTED LIVER DISEASES AND LABORATORY TESTS USED IN THE EVALUATION OF LIVER FUNCTION**

**Alpha-1 Antitrypsin Deficiency**

In individuals with unexplained and/or early onset emphysema or liver disease, alpha-1 antitrypsin deficiency should be considered. Alpha-1 antitrypsin is an antiprotease that protects the lungs from endogenous elastases, collagenases, and proteases. Deficiency of alpha-1 antitrypsin can produce early onset panlobular emphysema. The liver disease results from the inability to release a mutated alpha-1 antitrypsin protein.

Mutations in the \( \text{Pi} \) (protease inhibitor) gene \( \text{SERPINA1} \) result in alpha-1 antitrypsin deficiency. The normal allele is denoted as "M." A common abnormal allele is "Z." Homozygosity for \( Z \) (eg, \( Z/Z \)) causes alpha-1 antitrypsin deficiency. In some forms of alpha-1 antitrypsin deficiency where the enzyme is not synthesized at all within the hepatocyte, emphysema can develop without liver disease as defective enzyme is not present in the liver.

**Glycogen Storage Diseases**

GSDs are disorders of glycogen production (GSD type 0) or glycogen breakdown. They are a group of heterogenous disorders affecting the liver, skeletal muscle, and/or myocardium. GSD
types I, III, and VI can produce fasting hypoglycemia. GSD type I (von Gierke disease) results from a deficiency of glucose-6-phosphatase (type 1a). However, variants exist as type Ib: T1 transporter defects; type 1aSP: glucose-6-phosphatase stabilizing protein deficiency; type 1c: T2 beta transporter deficiency; and type 1d: GLUT7 glucose transporter deficiency. GSD type III (Cori or Forbes disease) is a deficiency of amylo-1,6 glucosidase. GSD type VI (Hers disease) results from a deficiency of liver phosphorylase or phosphorylase b kinase.

**Hemochromatosis**

Iron overload in the absence of chronic transfusion therapy most commonly results from hemochromatosis type 1 (HH1) that is inherited as an autosomal recessive disorder. HH1 results from mutations in the HFE gene that is encoded within the major histocompatibility complex located on the short arm of chromosome 6. Two possible genotypes cause HH1: C282Y/C282Y or C282Y/H63D. Homozygosity for H63D (H63D/H63D) does not cause clinical disease. HFE mutations lead to deficient hepatic secretion of hepcidin. In turn, hepcidin deficiency permits excessive expression of ferroportin with consequent hyperabsorption of iron from the GI tract.

Increased transferrin saturation is the earliest biochemical marker of hemochromatosis. Elevations in ferritin follow. Percent transferrin saturation is the recommended screening test. Elevated ferritin is not specific for iron overload. Ferritin is elevated as an acute-phase reactant, and ferritin is released from the liver with disease or injury and in patients with the metabolic syndrome.

HH1 has a population frequency of ~1 in 300, with a 5:1 to 7:1 excess of affected males over females. The onset of symptoms is typically between 40 and 50 years of age. Iron deposition occurs in the heart (potentially causing cardiac failure), liver (producing liver disease including cirrhosis), endocrine organs (causing diabetes, hypopituitarism, hypothyroidism, and/or hypogonadism), and skin. Arthropathy is another feature of HH1.

There are several other types of hemochromatosis in addition to HH1. HH2a results from hemojuvelin mutations, while HH2b is caused by primary hepcidin deficiency. HH2a and HH2b present in childhood. Mutations in the transferrin receptor 2 (TfR2) cause HH3. HH4 causes greater iron deposition in the reticuloendothelial system than in the solid organs and liver. HH4a is a consequence of loss of function ferroportin mutations. Aceruloplasminemia causes HH4b. Hyperabsorption of iron from the gastrointestinal tract can occur in various forms of anemia with ineffective erythropoiesis (eg, in cases of thalassemia and sideroblastic anemia). Hemochromatosis can be differentiated from transfusion-related iron overload by noting whether the patient has a history of repeated transfusions. Iron overload from transfusion and hemochromatosis rarely coexist.

**Wilson Disease**

Wilson disease is a rare autosomal recessive disorder estimated to affect 1 in 200,000 persons. Mutations in ATP7B result in copper overload with consequent copper deposition in the brain, liver, kidneys, and cornea (the Kayser–Fleischer ring). ATP7B is the product of the copper-transporting ATPase gene on chromosome 13q. ATP7B normally moves copper into the bile. In >90% of patients with Wilson disease, the ceruloplasmin level is decreased. Copper excretion is increased in the urine, and therefore urinary copper is a useful noninvasive test in the investigation of possible Wilson disease. Liver biopsy can provide a quantitative measure of the degree of copper overload, as elevated hepatic copper is highly supportive of the diagnosis of Wilson disease. The most common presentation of Wilson disease is chronic liver disease (including cirrhosis), but it can present as acute, fulminant hepatitis that may require liver transplantation for survival.

**Hepatocellular Carcinoma and Alpha-fetoprotein (AFP)**

AFP is the major plasma protein produced by the fetal liver early in gestation. In adults, in contrast, AFP concentrations are normally very low. AFP may be elevated in many circumstances. It may be transiently increased with acute liver disease or persistently increased in chronic liver disease and cirrhosis. In patients with chronic liver disease or cirrhosis, an elevated AFP should trigger evaluation of the patient for hepatocellular carcinoma. For this cancer, elevated AFP levels serve as a tumor marker with a 40% to 80% sensitivity.
Acute (fulminant) hepatic failure can result from a wide variety of insults, but the most common causes are acute viral hepatitis, toxins (eg, *Amanita phalloides* mushrooms), and poisonings (eg, acetaminophen).

**Hepatic Encephalopathy and Ammonia**

Ammonia is an end product that results from amino acid deamination. The urea cycle captures ammonia (and thus nitrogen) for excretion by the kidney in the form of urea. Significant impairments in liver function produce hyperammonemia. In turn, hyperammonemia is associated with hepatic encephalopathy. A characteristic physical finding in patients with a toxic or metabolic encephalopathy is asterixis (unintended jerking movements particularly of the hands when they are dorsiflexed).

**Cholestasis of Pregnancy and Serum Bile Acid**

Serum bile acid concentrations reflect the ability of the liver to remove bile acids from the circulation and excrete them into the bile as part of the normal bile enterohepatic recirculation. Impaired hepatocyte uptake or secretion of bile acids, and portosystemic shunting, can elevate serum bile acid levels. Serum bile acids are often measured in women with cholestasis of pregnancy; otherwise, serum bile acids are rarely measured as they add little valuable information to the standard tests of hepatic function thus far discussed. Many argue that the diagnosis of cholestasis of pregnancy can be readily established without the measurement of serum bile acids.

**Acute (Fulminant) Hepatic Failure**

Acute (fulminant) hepatic failure can result from a wide variety of insults, but the most common causes are acute viral hepatitis (eg, HBV and less commonly HAV), toxins (eg, *Amanita phalloides* mushrooms), and poisonings (eg, acetaminophen). Other causes of acute hepatic failure include adenovirus infection, varicella-zoster virus (VZV) infection, acute fatty liver of pregnancy, Wilson disease, Reye syndrome, and portal vein thrombosis.

In acute liver failure, the clinical course is rapid. Unless spontaneous recovery takes place or liver transplantation is performed, the outcome is fatal. Acute and chronic liver failure share many potential characteristics ([Table 16–9](#table16_9)): profound hyperbilirubinemia, coagulopathy (eg, bleeding with a prolonged PT and thrombocytopenia), hypoproteinemia (eg, hypoalbuminemia with edema), hypoglycemia, hyperammonemia with encephalopathy, and oliguric renal failure (the hepatorenal syndrome resulting from, in part, splanchnic vasodilation). Chronic liver failure

DIC, disseminated intravascular coagulation; GI, gastrointestinal; PT, prothrombin time.
is also associated with intrapulmonary shunting leading to hypoxia and clubbing of the digits (hepatopulmonary syndrome). Liver failure that occurs after 6 months of recognized liver disease is chronic liver failure.

**Cirrhosis**

Cirrhosis is the outcome of any chronic disorder of the liver parenchyma or intrahepatic biliary tract that causes continuous or repeated episodes of cellular necrosis and inflammation, followed by subsequent episodes of repair. At some point, recurrent injury to the liver can destroy the connective tissue that is the reticular structure of the liver. This results in scarring with the deposition of increasing amounts of collagen. Bridging fibrosis can disturb intrahepatic blood flow, leading to portal hypertension, with the consequent development of ascites and esophageal varices. The liver becomes small and firm from fibrosis, yet on physical examination the abdomen is distended because of ascites. In some patients, reopening of the umbilical vein occurs and produces periumbilical varices termed “caput medusa” (after the mythical Greek character Medusa). Cirrhosis can predispose to hepatocellular carcinoma. Histologically, proliferating hepatocytes appear as regenerating nodules among the fibrotic bands. Nodules can be small (<3 mm—micronodular) or large (>3 mm—macronodular).

Ethanol abuse is the most common cause of cirrhosis in Westernized countries, accounting for 60% to 70% of cases. Other causes include chronic viral hepatitis (~10%), biliary tract diseases (~5%-10%), and hereditary hemochromatosis (~5%). NAFL is increasingly being recognized as a cause of cryptogenic cirrhosis, that is, cirrhosis of otherwise unknown origin.

Patients with cirrhosis can experience severe functional liver impairment, also called “end-stage liver disease.” Such patients can have a mixed unconjugated and conjugated hyperbilirubinemia, profound hypoalbuminemia, hypoglycemia, coagulopathy (from decreased clotting factor production, decreased clearance of fibrin-split products, and thrombocytopenia), and hyperammonemia.

Laboratory data can indicate the degree of liver dysfunction. However, cirrhosis remains a clinical diagnosis until definitive diagnosis is established by the results of a liver biopsy.

**Primary Biliary Cirrhosis**

Primary biliary cirrhosis (PBC) affects the interlobular bile ducts and is a chronic autoimmune biliary tract disease with obstructive jaundice. Thus, patients with PBC show a conjugated hyperbilirubinemia and relative elevations in ALP exceeding the ALT and AST elevations. ALT and AST can be normal.

Approximately 95% of patients with PBC are positive for anti-mitochondrial antibodies (AMA). Portal inflammation and progressive scarring can progress to liver failure requiring liver transplantation. The condition most often affects women between the ages of 40 and 50 years.

**Primary Sclerosing Cholangitis**

PSC affects the larger bile ducts. Men are more commonly affected than women (70:30 ratio), with a mean age at onset near 40 years. Tests for AMA are negative in patients with PSC. Inflammatory bowel disease, such as Crohn disease or ulcerative colitis, is identified in about 75% of patients with PSC. The definitive diagnosis of PSC is made by liver biopsy.

**APPROACH TO THE PATIENT WITH LIVER DISEASE**

One reasonable approach to the evaluation of liver function is to first consider the bilirubin concentration (Figure 16–1 and Tables 16–3 to 16–6). If there is an unconjugated hyperbilirubinemia, possible hemolysis should be investigated. If this is absent, other causes of an unconjugated hyperbilirubinemia need to be considered, such as neonatal jaundice, Gilbert syndrome, and Crigler–Najjar syndrome.

If there is a conjugated hyperbilirubinemia, the liver enzymes can be used to separate hepatocellular disease (eg, predominant elevations in ALT and AST) from biliary tract disease.
(eg, predominant elevations in ALP, or if measured, GGT and 5′-NT). Disorders are then investigated based on their relative frequency and whether the disease is acute or chronic. Not noted in Figure 16–1 is end-stage liver disease in which there can be significant elevations in both the conjugated and unconjugated fractions. In the absence of hyperbilirubinemia, the focus on liver dysfunction becomes the pattern of enzyme elevation.

**REFERENCES**

Disorders involving the pancreas are generally divided into 2 categories. One group includes diseases of the exocrine portion of the pancreas, which secretes digestive enzymes into the gastrointestinal tract. The other category includes the disorders of the endocrine portion of the pancreas, which contains beta cells for secretion of insulin, alpha cells for secretion of glucagon, and delta cells for secretion of somatostatin. The cells that secrete hormones are arranged in islets within the exocrine pancreas.

The most frequently encountered disorders of the exocrine pancreas are pancreatitis and pancreatic neoplasms (usually cancer). Pancreatitis may be acute, or chronic with recurrent bouts of acute pancreatitis. Pancreatic tumors of the exocrine pancreas almost always originate in the pancreatic ductal epithelium. The major disease of the endocrine pancreas is diabetes mellitus (DM). Several neoplasms are also associated with the endocrine pancreas but are much rarer than those associated with the exocrine pancreas.
**ACUTE PANCREATITIS**

**Description**
Acute pancreatitis is a potentially lethal disorder associated with intracellular activation of digestive enzymes in the pancreas. This results in autodigestion of the pancreatic tissue by the powerful enzymes normally secreted into the gastrointestinal tract to degrade ingested foods. The damage to the pancreas can produce inflammation, edema, necrosis, hemorrhage, and liquefaction, and may obstruct the pancreatic duct and block the flow of pancreatic enzymes into the gastrointestinal tract. The obstruction further enhances the progression of acute pancreatitis. Clinically, a bout of acute pancreatitis is characterized by midepigastric pain frequently radiating to the back, nausea, and vomiting.

The cause of acute pancreatitis in the majority of cases is either alcohol abuse or gallstones. There are, however, other causes, such as hypertriglyceridemia, hypercalcemia, selected infections, obstructing pancreatic tumors, and trauma to the pancreas. Hereditary forms of acute pancreatitis have also been described due to mutations in the trypsinogen gene or the trypsin inhibitor gene. In addition, many medications have been associated with the development of acute pancreatitis. Selected examples are asparaginase, azathioprine, estrogens, furosemide, sulfonylamides, tetracycline, and thiazide diuretics. The mechanism of pancreatic injury following ingestion of these medications may be related to hypersensitivity to the drug or accumulation of a toxic drug metabolite in the pancreas. In about 20% of cases of acute pancreatitis, a specific cause cannot be identified. This is known as idiopathic acute pancreatitis.

**Diagnosis**
A large number of potential markers (carboxyester lipase, carboxypeptidase, trypsin, trypsinogen-2, pancreatitis-associated protein, trypsinogen activation peptide, C-reactive protein, and tumor necrosis factor) are discussed in the literature as possible for the diagnosis of acute pancreatitis; however, none of them are typically available in most hospital laboratories. In fact, acute pancreatitis is not solely diagnosed by a biochemical marker but rather by a combination of history, clinical presentation, and radiologic and laboratory findings (Table 17–1).

Nonspecific laboratory findings include, but are not limited to, aminotransferase elevations, mild-to-moderate leukocytosis with a shift toward immature forms, hyperglycemia, mild hyperbilirubinemia, and a decreased serum calcium level.

More specific biochemical tests used for the diagnosis are amylase and lipase. Historically, an amylase level greater than 3× the upper limit of normal was considered diagnostic for acute pancreatitis, and lipase findings were helpful but not as useful. The problem with lipase was the existence of a number of different assay methods and no standardization between them. This has changed. Current assays for lipase are more standardized, and the lipase assay has several characteristics that make it a better marker for acute pancreatitis.

Temporally, in acute pancreatitis, amylase will rise and fall over a shorter period of time (rise over 6-24 hours, peak at 48 hours, and normalize in 5-7 days). Lipase has different temporal kinetics (rise over 4-8 hours, peak at 24 hours, and normalize in 8-14 days). Therefore, it

In chronic pancreatitis, the amylase/creatinine clearance ratio can be increased even when the serum amylase is normal or only slightly elevated. The amylase/creatinine clearance ratio is: (urine amylase [U/L] × serum creatinine [mg/L])/serum amylase [U/L] × urine creatinine [mg/L] × 100.
is more possible to miss an amylase elevation than a lipase elevation. In addition, despite the fact that neither marker is organ specific for the pancreas, lipase has relatively greater pancreas specificity than amylase. There are a larger number of conditions that can result in non-pancreatitis hyperamylasemia than there are that can result in hyperlipasemia. Conditions associated with non-pancreatitis increases in both amylase and lipase include biliary disease, intestinal obstruction, pancreatic pseudocyst, and renal impairment. Clinical conditions associated with elevations in amylase without a corresponding increase in lipase include macroamylasemia, ruptured ectopic pregnancy, salivary gland disease, and abdominal and thoracic malignancies. Renal failure is the most common extrapancreatic condition associated with an elevated serum lipase level. About 80% of patients with renal failure have lipase levels 2 to 3 times the upper limit of the reference range, and about 5% have an elevation more than 5 times the upper limit of normal.

Amylase elevation greater than $3 \times$ the upper limit of normal is the cutoff often cited for the diagnosis of acute pancreatitis. Test characteristics for amylase in the diagnosis of acute pancreatitis range from 45% to 85% for sensitivity with specificities ranging from 90% to 99%. Test characteristics for lipase elevations have sensitivities and specificities greater than 95% for the diagnosis of acute pancreatitis.

In cases of hyperamylasemia where the clinical presentation does not support the diagnosis of acute pancreatitis, a urine amylase level may have clinical utility.

A urine amylase determination may be helpful in diagnosing pancreatic disorders, especially when the serum amylase level is normal or slightly elevated. As a general rule, urine amylase rises within 24 hours after an increase in serum amylase, and remains high for 7 to 10 days after the serum level returns to normal. Renal excretion of amylase depends on the glomerular filtration rate and, consequently, the urine amylase correlates with the creatinine clearance (CC). In acute pancreatitis, the clearance of amylase into the urine may be increased compared with creatinine, resulting in an increased (amylase/creatinine clearance [A/CC]) ratio. The A/CC ratio is determined using the following formula:

$$\text{Urine amylase (U/L)} \times \frac{\text{Serum creatinine (mg/L)}}{\text{Serum amylase (U/L)} \times \text{Urinary creatinine (mg/L)}} \times 100$$

Determination of the A/CC ratio involves simultaneous collection of serum and urine specimens but does not require a timed or complete 24-hour urine collection. The A/CC ratio becomes abnormal 1 to 2 days after an elevation of the serum amylase, and typically remains abnormal for as long as the urine amylase is high. Like the urine amylase level, the A/CC ratio remains elevated for 7 to 10 days after the serum amylase level returns to normal.

Macroamylasemia is an established cause for an elevated serum amylase value. Macroamylase is a complex of alpha-amylase and other molecules, which may be proteins or carbohydrates. Because of its large molecular size, macroamylase is not filtered by the glomerulus in the kidney. Consequently, it accumulates in the serum, and produces a chronically elevated serum amylase level. The presence of macroamylase has been shown to account for an elevated serum amylase level in 1% to 3% of patients. Because macroamylase does not enter the urine, the urine amylase level is normal or low, unlike the situation in acute and chronic pancreatitis in which the urine amylase level is usually elevated along with the serum activity. Thus, patients with macroamylasemia have a combination of elevated serum amylase levels and normal or low urine amylase levels.

Both pancreatic and salivary amylase have more than 1 isoenzyme alpha-amylase can be pancreatic or salivary. Amylase can be separated into its component isoenzymes by selective enzymatic or chemical inhibition and by electrophoresis. In acute pancreatitis, there is an increase in pancreas-derived isoenzymes in almost all patients, but isoenzyme analysis is rarely required for diagnosis.

A number of laboratory tests and computed tomography may be useful to assess prognosis in patients with acute pancreatitis. One system to assign prognosis in acute pancreatitis is the simplified Glasgow criteria. Features associated with a worse prognosis include age $>$ 55 years, white blood cell count $>$ 15,000/μL, LD $>$ 600 U/L, glucose $>$ 180 mg/dL, albumin $<$ 3.2 g/dL, calcium $<$ 8 mg/dL, arterial Po2 $<$ 60 mm Hg, and BUN $>$ 45 mg/dL.
**CHRONIC PANCREATITIS**

**Description**
Following an attack of acute pancreatitis, the patient may experience a complete recovery, have an additional recurrence without permanent damage to the pancreas, or suffer multiple recurrences leading to chronic pancreatitis and significant damage to the organ. In chronic pancreatitis, the cells that generate the digestive enzymes are destroyed and replaced with scar tissue, and the pancreatic ducts become dilated and filled with precipitated protein. Chronic pancreatitis can be divided into chronic calcifying pancreatitis and obstructive pancreatitis. Since chronic disease follows from recurrence of acute pancreatitis, chronic pancreatitis has various causes in adults. In the United States, the majority of cases of chronic pancreatitis are due to prolonged excessive alcohol consumption. Malnutrition-induced pancreatitis is more common in underdeveloped areas of the world. In children, the most common cause of chronic pancreatitis is cystic fibrosis (see Chapter 7).

**Diagnosis**
The diagnosis of chronic pancreatitis may be challenging because the disease can evolve subclinically over an extended period. The patient with chronic pancreatitis often has impaired glucose tolerance (IGT) or, in severe cases, DM. Additional manifestations include abdominal pain, weight loss, pancreatic calcifications on x-ray, and steatorrhea. The sensitivity of laboratory tests to diagnose chronic pancreatitis depends on the extent of pancreatic tissue destruction and the length of time over which the damage has occurred.

An elevated serum amylase level is much less informative to make a diagnosis of chronic pancreatitis than it is in the diagnosis of acute pancreatitis. In about one half of the patients with chronic pancreatitis, the serum amylase level remains within the normal range. In other patients with the disorder, the values may be borderline or only slightly elevated, raising the possibility of a nonpancreatic cause for the elevated amylase. In chronic pancreatitis, the urine amylase level may be elevated when the serum amylase is within the normal range or only slightly elevated. Measurement of a 72-hour fecal fat provides an index of pancreatic exocrine function. It is increased in severe chronic pancreatitis. However, the fecal fat test is neither sensitive nor specific. More recently, measurement of fecal elastase (decreased in chronic pancreatitis) and serum levels of trypsinogen (decreased in chronic pancreatitis) have been used as additional tests of pancreatic function.

The bentiromide test is a noninvasive test for assessing pancreatic function in patients suspected to have chronic pancreatitis. The test is based on the hydrolysis by chymotrypsin of a synthetic tripeptide, N-benzoyl-l-tyrosyl-p-aminobenzoic acid. The tripeptide, variously called bentiromide, NBT-PBA, or BTP, is administered orally, along with a test meal to stimulate pancreatic secretion. Chymotrypsin cleaves the p-aminobenzoic acid (PABA) molecule from the bentiromide in the duodenum. The PABA moiety is absorbed into the portal circulation, conjugated in the liver, and excreted by the kidneys as an arylamine. In the bentiromide test, the arylamines are quantitated in a 6-hour urine specimen, with the time started after the oral intake of bentiromide and the test meal. Decreased excretion (<50% of the test dose) suggests decreased absorption from the duodenum, which can occur with deficient activity of pancreatic chymotrypsin. The sensitivity of the test for diagnosis of chronic pancreatitis depends on the severity of the disease, with greater sensitivity of the test correlating with greater disease severity. Many nonpancreatic conditions, especially diseases of the kidney, are associated with a false-positive test result by decreasing the conjugation and/or excretion of the PABA metabolite in the urine. Conversely, a number of drugs (acetaminophen, lidocaine, procainamide, sunscreens containing PABA, and pancreatic enzyme supplements, as examples) may produce a falsely normal result in a patient with chronic pancreatitis, because these products can increase the amount of arylamine in the urine.

Imaging studies including abdominal plain films may demonstrate calcifications. Ultrasound and computed tomography scans are relatively sensitive and specific. Duodenal intubation using endoscopic retrograde cholangiopancreatography (ERCP), with injection of x-ray contrast medium into the common bile duct and pancreatic ducts, is the most sensitive test, but the test itself may induce pancreatitis and should therefore be reserved for selected cases.
More recently endoscopic ultrasound has gained favor, and it is equally sensitive and specific for chronic pancreatitis as ERCP.

**PANCREATIC TUMORS**

**Exocrine Pancreas Neoplasms**

**Description**

Masses within the pancreas can be either nonneoplastic or neoplastic. The nonneoplastic masses are almost always cystic. However, both benign and malignant pancreatic tumors may be cystic. A cyst can be congenital from abnormal development, but more often, it is a collection of pancreatic secretions and tissue debris following bouts of pancreatitis, and is known as a pseudocyst. In contrast to true cysts, pseudocysts lack an epithelial lining. Pancreatic cancer affects more than 30,000 adults in the United States annually and is usually rapidly fatal. The great majority of these tumors arise in the exocrine pancreas and histologically are ductal adenocarcinomas.

**Diagnosis**

CA 19-9 is the most widely used pancreatic tumor marker. CA 19-9 antigen is present in the normal adult and fetal pancreas, and it is also found in the esophagus, stomach, small intestine, gallbladder, bile duct, and salivary glands. For the diagnosis of pancreatic cancer, the reported sensitivity ranges from 70% to 92% with a specificity that ranges from 68% to 92%. The marker’s sensitivity is proportional to tumor size. Measuring the level of the CA 19-9 may be useful in patients with pancreatic cancer. In patients with early stage tumors, the CA 19-9 level is often normal. Therefore, the marker is of little value as a screening test. In patients with more advanced tumors, the CA 19-9 level is often elevated, and this finding may be helpful in suggesting a diagnosis of pancreatic cancer. CA 19-9 is most useful as an aid to monitor the patient response to therapy. However, CA 19-9 is not specific to pancreatic cancer and may be elevated in other types of gastrointestinal cancers and in some nonneoplastic disorders as well. Of note, CA 19-9 requires the presence of the Lewis blood group antigen for it to be expressed. Therefore, CA 19-9 will be naturally undetectable in 7% to 10% of the population.

**Endocrine Pancreas Neoplasms**

**Islet Cell Tumors**

**Description and Diagnosis**

Islet cell tumors, which may occur as a single mass or multiple masses, may be associated with hyperfunction of specific hormone-secreting cells within the islets of Langerhans of the pancreas. Some islet cell tumors are nonfunctional, and therefore may present only with symptoms of a mass lesion. Radiographic studies to identify the tumor and permit surgical removal are an important part of the evaluation of the patient for an islet cell tumor.

- Beta cell tumors are also known as insulinomas and are clinically significant when they produce enough insulin to induce hypoglycemia. The laboratory studies used in the detection of insulinoma include plasma glucose, C-peptide, insulin, and the insulin to glucose ratio. Hypoglycemia is discussed in detail below.

- Tumors of the pancreatic islets that secrete gastrin are known as gastrinomas. However, the most common site of a gastrinoma is the duodenum. An elevated serum gastrin level from a gastrin-secreting tumor is associated with the development of peptic ulcer disease because gastrin stimulates acid secretion as well as watery diarrhea and malabsorption. This constellation of clinical and laboratory findings constitutes Zollinger–Ellison syndrome. Patients with peptic ulcer disease who do not have a *Helicobacter pylori* infection or a history of nonsteroidal anti-inflammatory drug use may have Zollinger–Ellison syndrome and should be evaluated for a gastrinoma. Patients with Zollinger–Ellison syndrome may also have multiple endocrine neoplasia I, with islet cell tumors that produce a variety of hormones. The secreted hormones found, in descending order of frequency, are: gastrin, insulin, serotonin, and vasoactive intestinal peptide (VIP), which is associated with watery
diarrhea. The diagnosis of a gastrinoma is based on the finding of an elevation in serum gastrin while fasting in association with increased gastric acid secretion.

- Tumors of the alpha cells of the pancreatic islets, also known as glucagonomas, are associated with elevated serum levels of glucagon. These tumors can be associated with a characteristic migratory erythema, as well as glucose intolerance, weight loss, deep vein thrombosis, and depression.
- Tumors of the delta cells of the endocrine pancreas are known as somatostatinomas. These tumors are typically associated with diabetes-related symptoms, diarrhea, steatorrhea, cholelithiasis, and weight loss. These tumors are most often located in the duodenum or jejunum, rather than in the pancreas.
- Some islet cell tumors produce vasoactive intestinal peptide (VIP). These tumors, known as VIPomas, induce a syndrome of watery diarrhea, hypokalemia, hypochlorhydria, and acidosis (WDHHA syndrome). Serum VIP levels are elevated in patients with VIPomas.

### DIABETES MELLITUS

#### Description

DM represents a heterogeneous group of disorders with the common feature of hyperglycemia due to defects in insulin secretion, insulin action, or a combination of these 2 factors. Table 17–2 shows the criteria for the diagnosis of DM. Disease sequelae are not directly related to the degree of hyperglycemia as much as they are related to the acute and chronic effects of hyperglycemia on end-organ processes.

For the acute inpatient population hyperglycemia is associated with increased morbidities and poorer prognoses for almost every acute disease process, most notably, but far from limited to, sepsis, acute coronary syndromes, and surgical recovery. As a result, all hospitals have now implemented policies and procedures to minimize inpatient hyperglycemia for both the diabetic and nondiabetic patients under the umbrella term, “tight glycemic control.”

Chronic hyperglycemia has been strongly associated with the development of polyneuropathy, nephropathy, and retinopathy, as well as a reduced ability to fight infections. Almost 13% of Americans have DM, of which 40% are unaware of their disorder. A significant fraction will already have some degree of nephropathy, neuropathy, and/or retinopathy when they are first diagnosed with DM. Importantly, many of the complications of diabetes can be avoided through early diagnosis and aggressive management.

The American Diabetes Association (ADA) sponsored the formation of an Expert Committee on the Classification and Diagnosis of Diabetes Mellitus to establish guidelines. The World Health Organization (WHO) adopted these guidelines, and further refined the diagnostic criteria for gestational diabetes.

Central to the ADA guidelines are etiology-based rather than treatment-based definitions for type 1 and type 2 DM and other disorders of glucose regulation (Table 17–3). The treatment

</tbody>
</table>
can vary with the disease course. For instance, patients termed “noninsulin-dependent” diabetics may eventually require insulin to control their hyperglycemia. The categories type 1 and type 2 diabetes are now designated by Arabic, rather than by Roman numerals. The majority of patients (90%-95%) have type 2 diabetes.

**Diagnosis**

Hyperglycemia, by itself, does not establish a diagnosis of diabetes. A diagnosis of diabetes depends on whether normal physiologic homeostasis and normoglycemia recur after a glucose elevation, and the normal glucose level is maintained. Criteria have been established by the ADA and WHO to diagnose DM determined by age (pediatric vs adult) and pregnancy status (pregnant or not). Specifics between the ADA and WHO may differ, but the theme remains the same. In the United States, ADA criteria are used, and external to the United States, WHO criteria may be used. Table 17–4 shows high-risk individuals for whom diabetes screening is recommended by the ADA.

**Prediabetes**

Although not meeting criteria for diabetes, an intermediate group of subjects exist whose glucose levels are too high to be considered normal but not high enough to be classified as diabetic (Table 17–2). Patients with impaired fasting glucose (IFG) and/or impaired glucose tolerance (IGT) have a prediabetic condition, indicating a high risk for development of DM. In the absence of pregnancy, IFG and IGT are not clinical entities in their own right, but instead identify patients at risk for DM and its cardiovascular complications. Loss of 5% to 10% of body weight, exercise, and treatment with appropriate medications are measures taken to prevent or delay the onset of DM in patients with “prediabetes.” Of note, the “impaired criteria” have changed as more data have become available, and it is possible that they will change again, thereby shifting formerly “prediabetic” individuals into the “diabetic” category.

HDL, high-density lipoprotein.
As mentioned before, about half of all Americans with type 2 DM go undiagnosed and suffer from preventable complications of the disease. Therefore, the ADA has advocated screening everyone over 45 years old with a fasting plasma glucose (FPG) test, with a repeat test every 3 years if the results are negative. Screening of groups with high risk for DM has been proposed for individuals <45 years old (Table 17–4).

**DIABETES**

### Fasting Blood Glucose

The most commonly used laboratory test for the diagnosis of diabetes is the FPG, measured after at least 8 to 12 hours of fasting. The patient can drink water while fasting, but should abstain from eating, smoking, or taking medications. Acute illness, surgery, and hospitalization within the previous 8 weeks are relative contraindications to testing, as false-positive results can arise in these situations. The threshold of 125 mg/dL for the FPG test is lower than that used previously (140 mg/dL). The 125 mg/dL threshold corresponds to an epidemiological breakpoint, above which the risk for retinopathy and nephropathy increases dramatically. Patients with IFG have a FPG ranging from 110 to 125 mg/dL. This group is considered at risk for subsequent development of DM, as well as for cardiovascular disease.

Blood glucose levels in some fashion have been used for a long time as the diagnostic criteria for diabetes. However, in 2009, another biochemical marker was added: hemoglobin A1c (HbA1c). HbA1c had been in use for about 2 decades as a prognostic marker of chronic hyperglycosylation because it was shown that the degree of its elevation is directly proportional to the degree of end-organ hyperglycosylation, and, therefore, directly related to the degree of end-organ damage. In 2009, the International Expert Committee on the role of HbA1c in the diagnosis of diabetes concluded that the HbA1c assay may be a better means of diagnosing diabetes than the measurement of blood glucose. Up to that point, HbA1c assay methods and results showed wide variation. However, as the assays improved and variation in results from method to method decreased, it gained utility as a diagnostic marker of diabetes. The committee recommends that a diagnosis of diabetes can be made if the HbA1c level is ≥6.5% (see below and Table 17–2). However, they also recommend that the diagnosis of diabetes should be confirmed with a repeat HbA1c test if the first one is greater than 6.5%, unless the patient already has clinical symptoms of diabetes or a blood glucose level greater than 200 mg/dL, in which case a single value greater than 6.5% is adequate to establish the diagnosis.

### Oral Glucose Tolerance Test

If the clinical picture merits further testing for diabetes in a patient with a FPG ≤125 mg/dL, an oral glucose tolerance test (OGTT) is indicated. The patient should have a regular diet during the preceding 3 days, with a carbohydrate intake of at least 100 g per day. The patient’s activity should be unrestricted, and only severe illness or hospitalization represents relative contraindications. Minor illnesses with gastrointestinal manifestations are not significant. The glucose bolus for nonpregnant adults is 75 g of anhydrous glucose dissolved in 10 to 12 oz of water or a preformulated flavored drink containing 75 g of glucose, such as glucola. For children, 1.75 g of glucose per kilogram weight is administered, up to a maximum of 75 g. The bolus should be consumed over 5 minutes. The testing protocol has been simplified from previous versions to include only 2 specimens: a fasting specimen and one 2 hours after the bolus. A 2-hour postbolus plasma glucose level of ≥200 mg/dL is diagnostic of DM. A 2-hour postbolus plasma glucose level of ≥140 mg/dL but <200 mg/dL is found in patients with IGT. Patients in this group, like those with IFG, are considered at risk for subsequent development of DM as well as cardiovascular disease.

### Random Blood Glucose

A random plasma glucose level of ≥200 mg/dL, combined with symptoms of DM (polyuria, polydipsia, and unexplained weight loss), also can be used to establish a diagnosis of DM.
These criteria do not depend on the time since the last meal, but the test should not be done when the patient is acutely ill.

**DISEASE MONITORING**

**Hemoglobin A1c**

The measurement of glycohemoglobin, specifically HbA1c, is essential for monitoring the success of therapy for patients with DM. HbA1c is formed by the nonenzymatic linkage of glucose to hemoglobin. Glucose enters the red blood cell, and it becomes bound to hemoglobin. An aldime is first formed that then undergoes an Amadori rearrangement to form a stable ketoamine, which persists for the life span of the red blood cell (typically 120 days). The HbA1c concentration does not exhibit the wide diurnal fluctuations that occur with blood glucose. The blood glucose concentration varies substantially with exercise, food ingestion, and many other factors. The rate of formation of HbA1c is directly proportional to the glucose concentration in the blood. Because of this, the HbA1c concentration is a reflection of the glucose values over the preceding 8 to 12 weeks. HbA1c is primarily used for monitoring long-term glycemic status and to determine whether a diabetic patient has achieved adequate metabolic control.

In diabetic patients, the retinopathy incidence increases substantially at HbA1c values between 6.0% and 7.0%. There is a low prevalence of retinopathy at HbA1c levels less than 6.5%. A HbA1c value of <7% is widely recommended. The ADA recommends measurement of HbA1c at least twice per year in all persons with DM. As noted above, a report from the International Expert Committee in 2009 on the role of HbA1c concludes that large volumes of data from diverse populations provide strong justification for assigning a reproducible HbA1c level of >6.5% as adequate for the diagnosis of diabetes.

Blood specimens for all these tests should be collected in gray-top tubes, as the sodium fluoride anticoagulant will inhibit glycolysis. Without sodium fluoride, the metabolism of glucose by the white blood cells in a specimen can lower the plasma glucose levels by 5% to 7% per hour. Serum levels are comparable to plasma levels if the serum is separated from the cells within 1 hour and testing is performed within 8 hours. Capillary blood glucose levels are approximately 10 mg/dL lower than plasma levels when fasting, but are equal to or higher than plasma levels after a glucose load. For the diagnosis of DM from a circulating glucose concentration, a plasma sample is the preferred specimen.

Point-of-care glucose testing is widely available in inpatient, outpatient, and home use populations. It is a very convenient and a simple to use modality for monitoring blood glucose levels before meals, assessing potential bouts of hypoglycemia or hyperglycemia, and for monitoring compliance with personalized diabetic regimens. These devices are not recommended to establish diagnosis of diabetes.

**Other Markers**

Considerable attention is now focused on the detection of autoantibodies as a screening tool for asymptomatic individuals with a strong family history of type 1 DM. The presence of autoantibodies to 2 or more of the following—glutamic acid decarboxylase (GAD65), islet tyrosine phosphatase (ICA512), or insulin—is a strong predictor of progression to type 1 DM (greater than 50%). It remains to be shown, however, whether early intervention can slow or prevent the subsequent onset of disease. Therefore, the ADA does not currently advocate screening for diabetes with these tests.

An important aspect of the ADA classification system is the prognosis for the patients based upon the etiology of DM in a given patient. DM from certain causes, such as drug use or endocrine tumors, may be completely reversible. DM from other causes such as insulin receptor defects are not reversible, and are often difficult to manage. DM categorized as “other specific types of diabetes” in Table 17–3 are much rarer than type 1 or type 2 DM. These types deserve some consideration whenever a new diagnosis of DM is made, as shown in Table 17–5.
The treatment goals for patients with DM include the prevention of disease progression and complications. Tight glycemic control in type 1 diabetics, defined by an HbA1c value of <6.5%, lowers the risk for the development and progression of microvascular disease. Currently, some laboratories are reporting HbA1c values with an average glucose value estimate, calculated using a formula. This approach permits the HbA1c result to be interpreted using the same units used for daily glucose monitoring. Fructosamine, also known as glycosylated albumin, is used in some institutions as a measure of glycemic control, because it reflects control over a shorter time frame than the HbA1c level. Monitoring and managing dyslipidemia, using total cholesterol, low- and high-density lipoprotein, and triglycerides as indicators, may lower the risk of developing macrovascular disease for both type 1 and type 2 diabetics. Trace excretion of urinary albumin, termed “microalbuminuria,” is routinely measured in patients with DM as an early marker of nephropathy. This test is not usually a part of routine urinalysis, and must therefore be ordered as a microalbumin test, along with a creatinine level, on a random urine specimen (see Chapter 18).

GESTATIONAL DIABETES MELLITUS

Description
Gestational DM represents any level of glucose intolerance initially recognized during pregnancy, even if it may have been present but unrecognized before the pregnancy. When hyperglycemia occurs for the first time during pregnancy, it usually develops late in the second or in the third trimester. Most women will be normoglycemic after pregnancy. Among the complications of untreated gestational DM are macrosomia (birth weight >4000 g or 8.82 lb), intrauterine fetal demise, and pulmonary immaturity. Congenital malformations are increased only in women who have preexisting diabetes, which may or may not have been clinically appreciated. Approximately 1 in 25 pregnancies in the United States is complicated by gestational DM, with a higher incidence in some ethnic groups (up to 1 in 7 in Native Americans).

Diagnosis
Screening for gestational DM was previously recommended for all pregnant women. Some experts suggest that screening of women at low risk for gestational DM is not cost-effective, although others still advocate testing all pregnant women. These low-risk women are of Caucasian or Middle-Eastern ancestry, less than 25 years old, of normal weight, have no first-degree relatives with DM, and have no history of abnormal glucose metabolism. Women with a high risk for gestational DM should be evaluated as soon as feasible into the pregnancy. All other women should be screened between 24 and 28 weeks gestation, with the exception of women with clinical symptoms consistent with gestational DM before 24 weeks, who should be tested when symptoms appear.

The ADA criteria for screening are shown in Table 17–6. Patients with an abnormal finding with the screening OGTT (with 50 g glucose) must also have an abnormal confirmatory finding with the OGTT (with 100 g glucose) to warrant the diagnosis of gestational DM. If a patient has only 1 abnormal value during a confirmatory OGTT performed at 24 to 28 weeks of gestation, some authorities recommend repeating the test at 32 weeks. The WHO currently advocates a screening OGTT for gestational DM using a 75-g glucose bolus, which has been shown to be more sensitive at detecting women at risk than the test using 50 g. However, the ADA chose not to adopt this modification because of the wide use of the 50-g bolus.

| Table 17–5 Laboratory Evaluation for Selected Other Causes of Diabetes Mellitus |
|----------------------------------------|-------------------------------------------------|
| Etiology                               | Test(s) for Evaluation                          |
| Exocrine pancreatic disease           | Amylase, lipase                                 |
| Cushing syndrome                      | 24-Hour urine-free cortisol                     |
| Glucagonoma                           | Plasma glucagon                                 |
| Hyperthyroidism                       | Thyroid-stimulating hormone (TSH)               |
| Hemochromatosis                       | Iron, ferritin, total iron-binding capacity     |
Six weeks after the end of a pregnancy complicated by gestational DM, the woman should be retested. Normoglycemic women with a history of gestational DM should be rescreened at 3-year intervals, and women with IFG or IGT should be screened more frequently.

**HYPOGLYCEMIA**

**Description**

Hypoglycemia is a low plasma glucose state. Symptoms result from activation of the autonomic pathways and from inadequate glucose delivery to the central nervous system. This explains the clinical features of hypoglycemia that are, in the acute form, intermittent episodes of sweating, tachycardia, anxiety, dizziness, slurred speech, double vision, and confusion, with complete recovery on restoration of plasma glucose to normal levels.

The plasma glucose level in hypoglycemic patients decreases well below the reference range, often to less than 40 mg/dL. Hypoglycemia is most commonly observed in patients being treated for diabetes.

OGTT, oral glucose tolerance test; PG, plasma glucose.
• **Surreptitious insulin injection:** Patients who inject themselves with insulin to produce a hypoglycemic state will have the same hypoglycemic symptoms as patients with hypoglycemia from other causes. However, these patients can be differentiated from patients with insulinomas because, even though they have a high level of plasma insulin, they have decreased levels of C-peptide. In insulin used for injection, the C-peptide moiety is removed. The C-peptide is not present in patients with surreptitious insulin injection because the insulin found in their blood is not synthesized from proinsulin in their pancreas.

• **Excess administration of sulfonylureas:** As with insulin, patients who have purposely taken sulfonylureas (an oral antidiabetic medication) in greater than prescribed doses suffer from hypoglycemia. Because oral antidiabetic medications are not naturally occurring compounds, a high serum concentration of these medications can reveal excess intake.

• **Impaired liver function:** Hypoglycemia can also occur in the presence of liver disease, often when it is associated with excess alcohol intake or ingestion of certain medications.

### Diagnosis

To diagnose hypoglycemia, the following 3 criteria (known as Whipple’s triad) must be met:

- Characteristic signs and symptoms of hypoglycemia
- Blood glucose level below 45 to 50 mg/dL coincident with symptoms
- Symptom reversal within 15 to 45 minutes of the administration of glucose, in the absence of cerebral edema

A portion of this chapter appeared previously in Clinical Laboratory Reviews (a publication for the Massachusetts General Hospital physicians) 2000;8:2 and 1999;7:4. It has been included with permission.

  Novel Biomarkers of Acute Kidney Injury 396

OVERVIEW OF RENAL DISEASE

The homeostatic roles of the kidney include maintenance and regulation of fluid balance, acid/base and electrolyte balance (eg, sodium, potassium, chloride, bicarbonate, calcium, phosphate, and magnesium), conservation of glucose, amino acids, and proteins, the excretion of wastes, and the production of hormones such as erythropoietin and 1,25-dihydroxyvitamin D. The renal blood vessels provide blood to the glomerulus and the tubules for the generation of urine. The glomerulus filters blood to create a plasma ultrafiltrate by retaining cells and proteins, whereas the tubules “process” the plasma ultrafiltrate to urine, thereby concentrating wastes such as urea, creatinine, nitrogenous wastes, and hydrogen ions.

Renal disease is suggested by any of the following findings:

1. Nonspecific symptoms of malaise, headache, visual disturbances, nausea, or vomiting (eg, many of these findings suggest uremia or hypertension [see below]).
2. Flank pain (eg, from pyelonephritis), pain that radiates to the groin from the flank (eg, from ureteral colic as a result of nephrolithiasis), or simple dysuria (eg, from a lower urinary tract infection).
3. A reduction in the volume of urine output. In adults, oliguria, a pathologically reduced urine output, is defined as less than 500 mL of urine produced per day. Anuria, which is essentially absent urine production, is defined in adults as less than 100 mL of urine produced per day. In infants, oliguria can be defined as urine output of less than 1 mL/kg/h, and in children older than infants, oliguria is defined as urine output of less than 0.5 mL/kg/h.
4. Hematuria, red blood cell casts, white blood cell casts, proteinuria, proteinaceous casts, pyuria, or other abnormalities on urinalysis.
5. Discolored or malodorous urine (eg, from a urinary tract infection).
6. Elevations in the plasma or serum concentrations of creatinine or blood urea nitrogen (BUN).
7. Malar rash (eg, from systemic lupus erythematosus).
8. Hypertension.
9. Otherwise unexplained hypokalemia or hyperkalemia, hypocalcemia, hypophosphatemia or hyperphosphatemia, pathologic fractures, hypomagnesemia, acidosis, anemia, edema, or bleeding.

Renal function should be evaluated when patients are taking drugs that can damage the kidney (eg, gentamicin) or drugs whose metabolism and/or excretion is dependent on the kidney (eg, low-molecular-weight heparin).

Nitrogen retention, as shown by an elevated BUN concentration, is termed “azotemia.” Azotemia can be classified as prerenal, renal, or postrenal. Prerenal azotemia refers to conditions with reduced blood flow to the kidney, thereby reducing urine output and causing the retention of waste products. Examples of prerenal causes of azotemia are congestive heart failure, GI hemorrhage, renal artery stenosis, and severe dehydration.

Renal azotemia indicates that the kidney itself is dysfunctional. The number of individual causes of intrinsic renal disease is large. In the broad view, however, renal azotemia results from diseases of the renal blood vessels, glomerulus, tubules, or interstitium. Glomerulonephritides may be the result of a primary process in the kidney (eg, autoantibodies against the phospholipase A2 receptor causing membranous nephropathy) or a secondary disorder leading to glomerulonephritis (eg, anti-base membrane autoantibodies causing Goodpasture syndrome). A biopsy is often necessary to identify the type of glomerulonephritis (eg, lupus nephritis, acute postinfectious [poststreptococcal] glomerulonephritis, IgA nephropathy, hereditary nephritis, or rapidly progressive glomerulonephritis). The histopathologic characteristics of the different glomerulonephritides and nephropathies are described in textbooks of anatomic pathology (eg, podocyte effacement in minimal change, “tram-tracks” in membranoproliferative glomerulonephritis, IgA deposition in IgA nephropathy, and “basket weaving” in Alport syndrome). It is worth noting that IgA nephropathy can produce nephritis or nephrosis. Acute tubular necrosis can cause renal failure. This may occur as a result of exposure to a toxin or as a result of ischemic damage to the tubules.

Postrenal azotemia results from an anatomic obstruction to urine flow out of the kidney. The ureter, bladder outlet, or urethra may be obstructed by a stone (eg, nephrolithiasis), congenital anomaly, inflammatory lesion, or neoplasm.

Among prerenal, intrinsic renal, and postrenal-induced renal failure, the dominant etiology is prerenal.

Uremia, unlike azotemia, is a clinical term that describes the patient's signs and symptoms when symptomatic end-stage renal failure is present. Findings in uremia include fatigue, headache, restlessness, depression, altered sensorium, nausea, vomiting, diarrhea, hiccups, bleeding, edema, shortness of breath, and pulmonary edema. Left untreated, uremia progresses to coma and death. Renal failure produces a wide variety of adverse clinical and metabolic consequences (Table 18–1).

Chronic renal failure is a deterioration in renal function that persists for more than 3 months. It occurs with progressive renal damage, and is independent of the cause of kidney disease. Chronic renal failure is the ultimate consequence of the loss of functioning nephrons. The dominant etiologies of chronic renal failure in adults are multifactorial, as in patients with diabetes mellitus, hypertension, glomerulonephritis, pyelonephritis/interstitial nephritis, cystic kidney disease, and toxicity from drugs. A significant percentage of patients with chronic renal failure have no known etiology for their disease.

Renal function can be assessed using a variety of clinical laboratory analyses. Acid/base and electrolyte balance is initially assessed by ordering a profile of tests that includes sodium, potassium, chloride, total serum CO₂ (bicarbonate), BUN, creatinine, calcium, and glucose.

A more detailed analysis of acid/base balance would also include a measurement of arterial blood gases (pH, pCO₂, pO₂, and calculated bicarbonate) and urine pH.
CHAPTER 18  The Kidney

is assessed by measuring the patient’s hemoglobin, hematocrit, and red blood cell indices. The kidney’s role in producing active vitamin D, that is, 1,25-dihydroxyvitamin D, and controlling phosphate excretion is evaluated, in part, through measurements of serum calcium and albumin (or ionized calcium), phosphate, and parathyroid hormone (PTH). Measurements of 25-hydroxyvitamin D assess vitamin D stores. 1,25-Dihydroxyvitamin D levels reflect the most active form of vitamin D in the body. However, measurements of 1,25-dihydroxyvitamin D are rarely required.

Urinary tract infections are especially common in females. Females are more prone to urinary tract infections than men because in females the urethra is shorter, and the distance from the urethra to the anus is shorter than in males. Discussion of pathogenic organisms resulting in bacterial infections of the kidney and urinary tract appears in Chapter 5.

CLINICAL LABORATORY PARAMETERS

Creatinine

Creatinine is a breakdown product of creatine and phosphocreatine, also known as creatine phosphate. Creatine is produced in skeletal muscle, the kidney, and the pancreas and is then transported to the tissues, especially the skeletal muscle and brain, via the bloodstream. Within cells, creatine is phosphorylated to phosphocreatine via the enzymatic action of creatine kinase (CK). Phosphocreatine provides a ready, rapid source of energy. For example, phosphocreatine is used as a short-term energy source as required during a sprint.

With an approximate 1% to 2% daily turnover rate, creatine and phosphocreatine are metabolized to creatinine at a fairly constant rate. Therefore, the plasma concentration of creatinine is usually stable day to day. Creatinine can be measured in the clinical laboratory by its ability to form an orange-red-colored product in a chemical reaction with alkaline picric acid. This is the classic Jaffé reaction. Creatinine can also be measured enzymatically using creatininase. Modern alkaline picric acid methods have been improved to minimize interferences by other substances. Nonetheless, at this time creatinine measurements using the picric acid method can be falsely elevated by a number of substances including ketones, glucose, and various drugs, such as cephalosporins and sulfonamides. Using creatininase to measure creatinine, interferences are uncommon.

Creatinine is freely filtered. However, 10% of the total excreted creatinine is secreted by the tubules. Negligible amounts of creatinine are reabsorbed. The alkaline picric acid method overestimates serum creatinine by at least 10% because of endogenous positive interferences. Creatininase methods are calibrated to report a creatinine concentration comparable to creatinine measured by the alkaline picric acid method. Therefore, the creatininase methods used to measure serum or plasma creatinine also display a positive bias. Standardization of creatinine measurements among analyzers has become an important goal for laboratory medicine.

The creatinine concentration in blood is inversely related to glomerular filtration rate (GFR; see below). If the GFR declines by 50%, the plasma creatinine approximately doubles. The creatinine concentration is directly related to skeletal muscle mass. Creatinine is higher in males

The glomerulus is investigated by determining the GFR. GFR is the number of milliliters of body fluids cleared by the kidneys per unit time reported in mL/min.
than in females, and increases with protein intake and with creatine intake. Creatine is sometimes used as a "nutritional" supplement by body builders or athletes. The clearance of creatinine by the kidney is a suitable estimate of GFR that is universally used by physicians. In the research laboratory, inulin clearance is an accurate method for measuring GFR. However, inulin clearance measurements are not applicable to routine clinical medicine because inulin must be infused IV until a constant concentration is achieved. Also in the research laboratory, renal plasma flow (RPF) can be estimated by measuring para-aminohippurate (PAH) clearance. Both the RPF and GFR allow the filtration fraction to be calculated (eg, the fraction of plasma that passes through the kidney per unit time which crosses the glomerular capillary barrier to enter the Bowman space).

The Glomerular Filtration Rate and Creatinine Clearance

Laboratory evaluation of the kidney as discussed in this chapter centers on assessments of glomerular and tubular function. The glomerulus is investigated by determining the GFR. GFR is the number of milliliters of body fluid cleared by the kidneys per unit time reported in mL/min. Ideally, GFR is measured using a substance that is produced by the body at a constant rate that is freely filtered by the glomerulus and is neither secreted nor reabsorbed by the tubules (ie, inulin). As GFR is reduced, waste retention occurs. Measurable waste products excreted by the kidney include creatinine, urea, and uric acid. With a decline in the GFR, these waste products are retained and their circulating concentrations rise. Measurement of the GFR is a very important assessment of renal function. A steady decline in GFR can serve as a harbinger of eventual end-stage renal disease.

GFR measurements are most commonly based on the clearance of creatinine by the kidney. This entails a serum creatinine measurement and a concurrent timed urine collection for the measurement of excreted urinary creatinine and urine volume. In individuals aged 18 years and above, an estimate of the GFR (eGFR) can be calculated solely from the serum creatinine and various patient parameters such as age, sex, and ethnicity.

A complete urine collection is essential for an accurate determination of the creatinine clearance because the equation contains a measurement of urine volume. The blood sample for serum creatinine is usually collected at the beginning of the timed urine collection. The clearance is expressed in terms of volume of fluid cleared per unit time (eg, mL/min).

The basic formula for creatinine clearance is as follows (serum creatinine and plasma creatinine are used interchangeably in the formulae):

\[
\text{Urine creatinine} \times \frac{\text{Urine volume (mL)}}{\text{Collection time (minute)}}
\]

The clearance can be corrected for the patient’s body surface area to be compared with a standard body surface area of 1.73 m².

When corrected for body surface area, the formula for creatinine clearance is as follows:

\[
\text{Urine creatinine} \times \frac{\text{Urine volume (mL)}}{\text{Collection time (minute)}} \times \frac{1.73}{\text{Body surface area (m²)}}
\]

For creatinine clearance (see the above formula), a 12- or 24-hour urine specimen is collected.

The GFR in persons aged 18 years and above can be reliably estimated (also known as the eGFR) solely from the patient’s serum creatinine, age, gender, and ethnicity (eg, African American or non-African American). The use of the modification of diet in renal disease (MDRD) equation, which is:

\[
\text{eGFR} = 186(S_c)^{-1.154} \times \text{(Age)}^{-0.203} \times F
\]

where \( F = 0.742 \) for females and 1.210 for African Americans, provides GFR estimates comparable to measured creatinine clearance when the GFR is less than 60 mL/min/1.73 m². Because of difficulties in obtaining a complete timed urine collection, the National Kidney Foundation (NKF) advises that eGFR be used in place of creatinine clearance measurements when the GFR is between 15 and 60 mL/min/1.73 m². It is not presently advised that eGFR be calculated in children because pediatric equations are not as well validated, unlike the MDRD equation that has been well validated in adults.
The MDRD equation provides eGFR determinations that are reliable between 15 and 60 mL/min/1.73 m². However, below 15 mL/min/1.73 m² and above 60 mL/min/1.73 m², GFR should be estimated using the traditional creatinine clearance measurement. The lower limit of the reference range for GFR is 90 mL/min/1.73 m². However, the upper limit of the reportable eGFR is 60 mL/min/1.73 m². Therefore, there is a “gray” zone between the upper limit of the reportable eGFR and the lower limit of the reference interval (90 mL/min/1.73 m²). Therefore, it is practical to report eGFR values greater than 60 mL/min/1.73 m² as simply “greater than 60 mL/min/1.73 m²” with a comment that “the lower limit of the reference interval is 90 mL/min/1.73 m².”

Many pathologic renal and systemic conditions can reduce the GFR. As GFR declines, creatinine clearance can, however, begin to overestimate GFR. This is because the fraction of the creatinine that is secreted by the tubules becomes a proportionately higher percentage of the urine creatinine excreted as GFR declines. However, since clinical practice is almost always based on assessment of the creatinine clearance, the difference between the “true” GFR and the creatinine clearance as a reflection of the GFR is usually not problematic when making clinical judgments.

The development of renal impairment is frequently unrecognized until late in its course, when intervention is less likely to be successful. Screening for reductions in GFR has recently been championed by the NKF. The NKF provides guidelines for the interpretation of the GFR result (Table 18–2). It defines kidney damage as any pathologic kidney abnormality reflected by a marker of damage, as shown in a blood, urine, or imaging study. Kidney damage that is present for more than 3 months is termed “chronic” kidney damage.

The NKF stresses that the creatinine clearance (unlike the eGFR) does provide useful information in estimating the GFR in individuals who have exceptional dietary intakes (such as those on vegetarian diets or those taking creatine supplements) or muscle mass changes (such as people with amputations, malnutrition, or wasting conditions). Creatinine clearance measurements are also valuable when deciding on the initiation of dialysis. This decision is made when the GFR is <15 mL/min/1.73 m²; the eGFR is not reliable in this setting.

Urea and the Blood Urea Nitrogen
Urea is produced by the liver to create a metabolite of ammonia (nitrogen) that can be excreted in the urine. The nitrogen in ammonia is derived from the deamination of amino acids.

The initially developed laboratory measurements of urea depended on liberating nitrogen from urea in whole blood. Therefore, the term “BUN” was created. However, modern laboratory methods actually measure urea in serum or plasma (and not whole blood) and back-calculate the nitrogen content, yet the term “BUN” has persisted.
The Blood Urea Nitrogen/Creatinine Ratio

If either the creatinine or BUN concentrations are above the upper limit of the reference interval, it is advised that the BUN to creatinine ratio (BUN/Cr) be calculated (Table 18–3). The normal BUN/Cr ratio is between 10:1 and 20:1. The ratio is helpful in determining the cause of renal impairment.

If the BUN/Cr ratio is 20:1 or higher, prerenal azotemia is likely to be present. Prerenal azotemia results from a reduction in the GFR while the kidney tubules are functioning.

The explanation why the BUN rises to a greater extent than creatinine involves 2 observations: 1) renal tubular secretion of creatinine persists even as GFR declines, opposing what would otherwise be a rise in serum creatinine, and 2) with decreased renal blood flow, the rate of capillary blood flow around the renal tubules is reduced, providing more time for the reabsorption of urea out of the urine in the tubules and back into the circulation, raising the serum BUN concentration.

When the BUN/Cr ratio is near 10:1 and creatinine and/or BUN are elevated, renal azotemia is likely, assuming that a chronic urinary tract obstruction has been excluded. In cases of renal azotemia, the BUN and creatinine rise proportionate to one another because, in part, tubular dysfunction will not maintain the tubular secretion of creatinine.

In the early phase of postrenal obstruction, the BUN/Cr ratio is ~20:1 because urea is reabsorbed from urine that is “stagnant” in the excretory system because of the anatomic obstruction. Therefore, if the BUN/Cr ratio is elevated at the time of patient presentation, the treating physician is obligated to consider the possibility of an anatomic obstruction to urine flow, as well as prerenal azotemia. If there is persistent urinary tract obstruction, postrenal azotemia can evolve into renal azotemia from damage to the kidneys. Obstruction appears to trigger inflammation in the glomerulus. If renal impairment then supervenes, the BUN/Cr ratio would fall to 10:1, similar to other conditions associated with intrinsic renal disease.

Urine Protein Quantitation

The general health of the kidney is assessed in part by the measurement of urinary protein excretion. In normal adults, 24-hour urinary protein excretion does not exceed 150 mg. If one assumes that a normal adult urine output is 1500 mL per day and a maximum of 150 mg of protein is excreted per day, the urine protein concentration should not exceed approximately 10 mg/dL. Elevated concentrations of protein in the urine can result from glomerular disease, tubular disease, overflow from elevated concentrations of plasma proteins, such as immunoglobulins or immunoglobulin light chains in patients with myeloma, urinary tract inflammation, as found in interstitial nephritis or urinary tract infection, trauma, or neoplasia.
In adults, proteinuria greater than 1 g per day is considered to be very significant clinically. Levels of protein excretion of 3.5 g per day or greater are consistent with nephrosis. Nephrosis is the clinical syndrome of massive proteinuria, hypoalbuminemia, edema, and hyperlipidemia. Primary renal diseases causing nephrosis include minimal-change disease, focal segmental glomerulosclerosis, membranous nephropathy, membranoproliferative glomerulonephritis, and IgA nephropathy. Secondary causes of nephrosis include diabetes mellitus, amyloidosis, lupus, drugs (eg, gold, penicillamine, heroin), infections (eg, malaria, syphilis, HBV, HIV), and malignancy (eg, carcinoma, melanoma).

In children, an elevated level of urinary protein excretion is >4 mg/m²/h. Nephrotic range proteinuria in children can be defined as >40 mg/m²/h.

The most cost-effective way to initially screen for proteinuria is urine protein dipstick testing. In this semiquantitative system, proteinuria is reported as negative, trace (10-20 mg/dL), 1+ (30 mg/dL), 2+ (100 mg/dL), 3+ (300 mg/dL), or 4+ (1000-2000 mg/dL). Urine dipsticks for protein measurements are relatively insensitive to immunoglobulin light chains and, thus, a negative dipstick does not exclude Bence Jones (monoclonal light chain) proteinuria. A more accurate measure of proteinuria can be made using a 24-hour urine sample. The urine protein concentration in milligrams per deciliter is multiplied by the urine volume in milliliters per 24 hours yielding milligrams of protein excreted per 24 hours.

Minimal but persistent amounts of albumin excretion in the urine (eg, microalbuminuria) are associated with diabetic nephropathy and with hypertensive renal damage. For this reason, people with diabetes mellitus are screened for minimal albumin excretion, also known as microalbuminuria. The albumin measurement is carried out using an immunos assay to provide analytical sensitivity, accuracy, and reproducibility. Microalbuminuria can be reported as the albumin to creatinine ratio obtained on a random urine sample, the albumin excretion in milligrams per minute on a timed urine sample collection (eg, a 4-, 6-, or 12-hour collection), or the albumin excretion per 24 hours when a 24-hour urine sample is collected. Table 18–4 provides an interpretation of microalbumin results.

It is recommended that all patients with type 2 diabetes mellitus be tested yearly for microalbuminuria from the time of diagnosis. For type 1 diabetes mellitus patients, testing is recommended to be performed annually beginning 5 years after the diagnosis of diabetes mellitus. Screening can begin with protein dipstick testing. If the dipstick is positive, microalbumin testing can be bypassed and testing should proceed to a 24-hour urine collection for the measurement of urine protein excretion. For patients with a negative dipstick result for proteinuria, microalbuminuria testing can be performed. If microalbuminuria is detected, a second sample should be obtained within 3 months. If the second sample does not display microalbuminuria, a third, “tie-breaker” sample is obtained. Thus, microalbuminuria must be present in 2 of 2 or in 2 of 3 samples to classify the patient as having persistent microalbuminuria.

With persistent microalbuminuria, the diabetic patient is diagnosed with stage 3 (eg, incipient) diabetic nephropathy (Table 18–5). Stage 1 nephropathy immediately follows the diagnosis of type 1 diabetes mellitus and is characterized by renal hypertrophy and hyperfiltration. These patients have an elevated GFR from the expanded plasma volume induced by hyperosmolality caused by hyperglycemia. With the initiation of insulin treatment, stage 1 resolves but clinically silent histologic changes subsequently occur in the glomerulus with mesangial hypertrophy and thickening of the glomerular basement membrane as observed on electron microscopy. This is stage 2 diabetic nephropathy. With the recognition of incipient nephropathy (stage 3) and intervention with improved glycemic control and the administration of antihypertensive drugs

| Table 18–4 Interpretation of Albumin Excretion in the Urine |
|-----------------------------|-----------------|------------------|-----------------|
| Units                      | Normal          | Microalbuminuria | Clinical Albuminuria |
| Spot collection            | μg/mg Cr        | <30              | 30-299           | ≥300           |
| Timed urine                | μg/min          | <20              | 20-199           | ≥200           |
| 24-Hour urine              | mg/24 h         | <30              | 30-299           | ≥300           |

Cr, creatinine.
(eg, angiotensin-converting enzyme inhibitors and angiotensin II receptor blockers), further progression to frank diabetic nephropathy can be averted or at least delayed. Proteinuria by dipstick, a falling GFR, and persistent hypertension identify stage 4 diabetic nephropathy. Stage 5 nephropathy is characterized by the development of end-stage renal failure eventually requiring either dialysis or transplantation.

**Patterns of Proteinuria**

When proteinuria is diagnosed, the subsequent diagnostic issues concern the cause of the proteinuria and the structural portion of the kidney that is functionally impaired. The glomerulus normally retains all plasma proteins with a molecular weight of greater than \( \sim 100,000 \text{ Da} \) (Table 18–6). Variable amounts of plasma proteins with molecular weights between \( \sim 10,000 \) and \( \sim 100,000 \text{ Da} \) are excreted into the urine. This includes albumin with a molecular weight of \( \sim 69,000 \text{ Da} \) and free immunoglobulin light chains with a molecular weight of \( \sim 25,000 \text{ Da} \). Plasma proteins below \( \sim 10,000 \text{ Da} \), such as insulin, are essentially freely filtered by the kidney.

Urine protein electrophoresis can identify the following patterns of protein loss: glomerular, tubular, overflow, and nonselective proteinuria. Glomerular proteinuria is characterized by albuminuria and the excretion of beta globulins, notably transferrin. Tubular proteinuria is recognized in urine protein electrophoresis by an alpha-2 doublet in addition to increased albumin excretion. Overflow proteinuria can result from a monoclonal immunoglobulin in high concentration in the plasma that “spills over” into the urine. For example, free monoclonal antibody light chains are detected by urine protein electrophoresis as an “M-spike,” a band of restricted mobility, and confirmed to be present by immunofixation electrophoresis (IFE). The light chain loss occurs because the ability of the tubules to reabsorb filtered protein is exceeded at high levels of proteinuria. With extensive renal injury, intact monoclonal immunoglobulins can be lost. Persistent glomerular proteinuria can injure the tubule, later resulting in a combined glomerular and tubular proteinuria. The excretion of multiple low-molecular-weight proteins that arise as part of the inflammatory acute-phase response can also produce overflow proteinuria. Nonselective proteinuria, which can occur with severe renal dysfunction, is identified when the urine protein electrophoresis pattern is similar to that of serum.

**The Fractional Excretion of Sodium as an Indicator of Tubular Function**

Tubular dysfunction can result in many abnormalities: glycosuria, amino aciduria, renal tubular acidosis (bicarbonate wasting or failure to generate new bicarbonate), electrolyte wasting (eg, hypernatremia, hypokalemia, and hypophosphatemia), and tubular proteinuria (see above). A readily available test of the resorptive function of the tubules is the “fractional excretion of sodium (FENa).”

FENa is calculated using creatinine and sodium measurements in serum or plasma and a simultaneously collected spot urine. The equation for the FENa is given as follows:

\[
\text{FENa} = \frac{[U_{Na^+}] \times [S_{Cr}]}{[S_{Na^+}] \times [U_{Cr}]} \times 100
\]

A readily available test of the resorptive function of the tubules is the “fractional excretion of sodium (FENa).” FENa is calculated using creatinine and sodium measurements in serum or plasma and a simultaneously collected spot urine.

**TABLE 18–5 Laboratory and Blood Pressure Findings in Diabetic Nephropathy**
The unit is percent sodium excreted (%). Normally the FENa is less than 1%. If there is tubular disease or injury, such as acute tubular necrosis, sodium wasting will occur and the FENa can exceed 1%. Tubular reabsorption of sodium is 100% minus the FENa. FENa calculations are not valid when patients are treated with diuretics because the diuretic will induce urinary sodium loss.

**Urinalysis**

Examination of the physical, chemical, and microscopic contents of urine constitutes urinalysis testing. The physical characteristics of the urine include its color, clarity, and specific gravity. Chemical analyses of urine include pH and detection of glucose, protein, blood, ketones, bilirubin, urobilinogen, nitrite, and leukocyte esterase. The microscopic examination is an assessment for cells, bacteria, crystals, casts, lipids, and contaminants.

If the urine dipstick is completely normal, some laboratories will not perform the microscopic examination. A urinalysis should complement BUN and creatinine testing in any patient undergoing a renal evaluation.

Also see serum protein electrophoresis in Chapters 2 and 3.
The clinical significance of positive findings in urinalysis studies is briefly detailed below.

Normal urine is straw-colored. With dehydration, the color intensifies. With higher levels of fluid intake, the straw color is less intense. The color of normal urine is produced largely by pigments present in the diet, such as the pigments in vegetables, as well as metabolites of bile. Patients with elevated urine bilirubin or urobilinogen can have urine that is darkly colored, or some patients produce green urine because of the oxidation of bilirubin to biliverdin.

The dipstick for blood reacts with heme. Heme is detected whenever red blood cells, hemoglobin, and/or myoglobin are present in urine. Therefore, dipstick positivity for blood does not identify whether red blood cells, hemoglobin, or myoglobin are present singly or in combination.

Hematuria refers to blood in the urine. It may be plainly visible (gross hematuria) or red blood cells may only be visible microscopically (microscopic hematuria). On a fresh urine sample, microscopic examination can reveal the presence of red blood cells and/or red blood cell casts. If red blood cell casts are present, nephritis or severe tubular injury is likely. Red blood cells in the absence of casts indicate bleeding into the urinary tract or the presence of a hemorrhagic coagulopathy. Casts are fragile, and therefore they are most likely to be found in a fresh, early morning urine specimen. If red blood cells are present in the urine but sample analysis is delayed, casts can fall apart and cells can lyse. Therefore, immediate analysis of a recently collected urine is best.

In a fresh urine sample lacking red blood cells but tests positive for blood, either hemoglobin or myoglobin is present. Free hemoglobin can enter the urine in cases of intravascular hemolysis. Myoglobin is released with muscle disease. Trauma can release large amounts of myoglobin into the blood. Both hemoglobin and myoglobin are toxic to the renal tubules.

Hemoglobin and myoglobin can be distinguished by precipitation methods and via centrifugation. In the precipitation methods, saturated ammonium sulfate is added, which precipitates hemoglobin but not myoglobin. Therefore, after precipitation if the dipstick for blood is positive, myoglobin is present. In centrifugation methods, the urine sample is centrifuged after application over a filter that retains hemoglobin but permits myoglobin to enter the infranatant. If the infranatant is dipstick positive for blood, myoglobin is present.

Proteinuria is thoroughly described earlier in this chapter.

Pyuria refers to increased white blood cells in the microscopic urine sediment. This is often considered to be at least 5 white blood cells per high-powered field. A test for leukocyte esterase enzyme activity, found in neutrophils, is on most urinalysis strips and can detect this activity whether the neutrophil is intact or disrupted. White blood cell casts originate in the tubules similar to red blood cell casts. White blood cell casts are consistent with pyelonephritis or noninfectious interstitial inflammation.

Urinary casts are formed in the kidney tubules and are indicators of renal disease. Cellular casts can be formed by red blood cells, white blood cells, or renal tubular (epithelial) cells. Granular casts, which do not contain intact cells, and waxy casts (both derived from degenerating tubular cells) can also be found in patients with kidney disease. Hyaline casts are composed of protein. They can be observed in the absence of disease.

Bacteriuria may be detected by a nitrite test on a urinalysis reagent strip, which is sensitive to the presence of clinically significant urinary bacteria concentrations. However, not all bacteria convert nitrates to nitrites. Also the urine must be retained in the bladder for some hours (approximately 4 hours or more) for this conversion to occur. Bacteriuria is often asymptomatic but a positive test result may reflect bacterial infection nonetheless. It is frequently accompanied by pyuria.

Urine glucose is not useful to diagnose or monitor patients with diabetes mellitus. There is only an approximate association between the level of plasma glucose and urinary glucose, as the renal threshold for glucose varies considerably among different individuals. This being said, if glycosuria is detected on a routine urinalysis, diabetes mellitus should be considered as a possible explanation. Trace glycosuria can be observed in normal pregnancies in the absence of diabetes mellitus because there is a reduction in the tubular threshold for the reabsorption of glucose during pregnancy.

Urine pH can be altered by conditions associated with metabolic acidosis or alkalosis. Freshly collected urine specimens should have a pH between 5.0 and 6.5. A urine pH greater than 8.0 suggests delayed analysis or bacterial contamination. On standing in an open container, CO₂ leaves...
the urine raising the pH. Bacteria can cleave urea to ammonia (NH$_3$) and CO$_2$. When ammonia reacts with water, ammonium ion (NH$_4^+$) and hydroxyl ion (OH$^-$) are formed. Increased hydroxyl ion raises the pH.

Urine specific gravity is defined as the ratio of the weight of urine to the weight of an equal volume of water. It provides an assessment of the capacity of renal tubules to concentrate or to dilute urine. The specific gravity of urine should range between 1.003 and 1.035.

Bilirubin should not be present in the urine, and when it is detected, it is indicative of liver dysfunction or biliary obstruction. Bilirubin present in the urine is conjugated, water-soluble bilirubin.

Urinary urobilinogen is derived from bilirubin that is degraded by bacteria in the gastrointestinal tract. Urobilinogen then undergoes enterohepatic recirculation to then be excreted in the urine. Conditions in which there is an elevated urinary urobilinogen include liver disease, because of failure to remove the urobilinogen from the blood, and hemolytic anemia in which bilirubin production increases the generation of urobilinogen.

Ketones most commonly appear in the urine of patients who have poorly controlled diabetes mellitus, although they can also appear in stressed hospitalized patients who do not have diabetes mellitus and in fasting patients.

**Stones and Crystals Found in Urine**

The process of kidney stone formation is known as nephrolithiasis or urolithiasis. The presence of a kidney stone is often associated with severe pain radiating from the back and/or flank into the groin. Although most stones pass spontaneously, some do not. The size of the stone, among other factors, determines whether the stone will be passed or retained. Stones can form when there is increased excretion of the components found in stones or the urinary volume is decreased, leading to elevated concentrations of urinary components. Calcium, phosphate, and oxalate are the most commonly found chemical constituents in renal stones, and less commonly identified are urate and cystine.

If there is a sufficient amount of stone material for analysis, the composition of the stone can be determined. The value of knowing the composition of the stone is that information may be derived about the contributing factors to its formation. This can lead to treatment, sometimes involving dietary modification.

An elevated concentration of calcium in the urine can lead to the generation of calcium oxalate and calcium phosphate stones. An increased concentration of oxalate in the urine can occur in patients who have an excess absorption of dietary oxalate. In Crohn disease, there is increased absorption of oxalate from the ileum. Cystine can accumulate in the urine when there is defective transport of cystine out of the urine by the proximal tubules, allowing cystine to reach a concentration at which it becomes insoluble in the urine. High concentrations of urinary uric acid are found in patients with gout, and such patients are predisposed to form urate stones, particularly when the urine has a pH below 5.4. Stones consisting of calcium carbonate and struvite (MgNH$_4$PO$_4$) can occur in patients with urinary tract infections, particularly those caused by *Proteus*. Many patients presenting with a kidney stone have no identifiable underlying cause for its formation.

Crystals are frequently observed in a microscopic urine examination, and the majority are normal urinary components. However, in patients predisposed to forming kidney stones, the crystals may provide information that suggests the composition of the stone.

**Selected Additional Tests to Evaluate Renal Function**

**Cystatin C**

Cystatin C is a low-molecular-weight protein of ~13,000 Da that is produced by the body at a constant rate. Because cystatin C appears to be cleared solely by the kidney, elevated cystatin C levels are inversely proportional to the GFR. Epidemiologic data demonstrate that increased cystatin C levels are positively correlated with mortality. Because creatinine measurements are readily available (and inexpensive), cystatin C is unlikely to replace creatinine clearance measurements in the near term.
Uric Acid
While it is true that uric acid concentrations rise as the GFR declines, uric acid is not a very helpful indicator of GFR. This is because serum uric acid levels vary widely according to diet. High-protein diets elevate uric acid, as does high cellular turnover. Neoplasias with high cellular turnover rates elevate uric acid as does cell death from chemotherapy. Uric acid levels are markedly affected by variation in the rates of production and reabsorption of uric acid, as found in patients with gout.

Calcium, Phosphate, and Parathyroid Hormone
Calcium, phosphate, and bone metabolism is impaired in patients with renal failure. PTH normally stimulates a net decrease in calcium excretion in the urine, as it stimulates calcium reabsorption in the distal tubule. PTH increases phosphate excretion into the urine, as it decreases the loss of calcium into urine. See Chapter 22 for additional information on this topic.

Novel Biomarkers of Acute Kidney Injury
Presently a major goal of nephrology is to identify an early marker of acute kidney injury that will predict the development of acute renal failure. Such marker(s) would be analogous to markers of myocardial necrosis (eg, cardiac troponin T or cardiac troponin I). Many markers are under investigation including lipocalins (eg, neutrophil gelatinase-associated lipocalin-2; NGAL), heat shock proteins (eg, HSP72), interleukins (eg, IL-18), and a variety of other proteins (eg, kidney injury molecule-1, cystatin C (as noted above), N-acetyl-β-d-glucosaminidase, and liver fatty acid-binding protein). One diagnostics company offers an assay for urinary NGAL on their automated immunoassay platform. Presently, none of these markers are used routinely and their diagnostic and prognostic values are under investigation.

LEARNING OBJECTIVES

1. Understand how prostate-specific antigen (PSA) is used in the monitoring of prostate cancer, and controversies regarding use of PSA as a cancer screening test.
2. Learn how β-human chorionic gonadotropin (β-hCG), alpha-fetoprotein (AFP) and lactate dehydrogenase (LD) levels are used in the management of patients with certain germ cell testicular tumors.
3. Learn how tests of androgen metabolism and regulation can be used in diagnosis of male gonadal dysfunction.
4. Learn the major causes of male infertility, and the major tests involved in semen analysis.

CHAPTER OUTLINE

Introduction 397
Prostate Cancer 397
   Prostate-specific Antigen 398
Testicular Cancer 399
   Male Gonadal Dysfunction 400
   Male Infertility 401

INTRODUCTION

The penis, testes, epididymis, vas deferens, seminal vesicles, and the prostate comprise the male genital tract. Circulating markers have been identified for prostate cancer and testicular cancer. For that reason, a discussion of these tumors and their serum markers is presented in this chapter (Table 19–1). Also, laboratory tests are often used in evaluating men with gonadal dysfunction and men who may be subfertile, infertile, or sterile. A summary of these tests and their usage is also provided. The male genital tract is the site of many infectious diseases, a significant proportion of which are sexually transmitted. These are discussed in Chapter 5.

PROSTATE CANCER

Description

Prostate cancer is a common malignancy of men that increases in incidence with age. It is second only to nonmelanoma skin cancer as the most commonly diagnosed cancer in men (over 150 cases/100,000 men), and second only to lung cancer as the most common cause of cancer death in males. However, most cases are slowly progressive and do not cause major morbidity or lead to death. A major unresolved challenge is differentiating the rapidly progressive and fatal form of prostate cancer from the indolent forms that do not cause death. Mortality associated with the disease has been decreasing. This has been attributed by some to early detection, although
a systematic review of published studies has shown no consistent difference in prostate cancer mortality between those who have and those who have not been screened for the disease. The use of laboratory assays to measure the serum prostate-specific antigen (PSA) concentration, however, has had the greatest impact on increased detection of this cancer.

**Prostate-specific Antigen**

PSA is a serine protease enzyme (also called human kallikrein 3) synthesized almost exclusively by the prostate and secreted into the seminal fluid. A small amount is also found in the blood. In the blood, PSA is largely bound to enzyme inhibitor proteins such as alpha_1_ antichymotrypsin and alpha_2_ macroglobulin. A small fraction of circulating PSA is free (unbound).

PSA levels in blood generally correlate with the size of the prostate. The larger the gland, the higher the PSA value. PSA may also increase transiently after a vigorous rectal examination, and after prostate biopsy or surgery. Inflammation and infarction of the prostate can also cause increased PSA, which returns to normal gradually. It is therefore recommended that elevated PSA levels should be confirmed by repeat measurement (at least 2–3 months apart) before any other action is taken, to exclude 1 of these insignificant causes of high PSA.

Prostate disease is common in men after the age of 50 years, and by age 70 years the majority of men have prostate disease. The 2 major diseases of the aging prostate are prostate carcinoma and benign prostatic hyperplasia (BPH). A number of factors have been evaluated to try to distinguish between these causes of increased prostate size and/or increased PSA levels. Both prostate cancer and BPH contribute to elevations in serum PSA.

In most laboratories, the PSA threshold considered positive for cancer screening is >4 ng/mL; above that threshold concentration, the positive predictive value for prostate cancer (the likelihood that cancer will be found in a biopsied prostate gland) is about 30%. In general, PSA is increased to a greater extent in prostate cancer than in BPH; PSA is rarely >20 ng/mL in BPH, and in only about 10% of cases is it >10 ng/mL, so higher values suggest cancer. A high PSA in a man with a small prostate gland on rectal examination is more worrisome for cancer than a similar PSA value in a person with a very large gland. The ratio of free PSA/total PSA is a better diagnostic marker for prostate cancer than total PSA; in general, a lower proportion of free PSA is found in patients with prostate cancer, but there is a wide overlap in values.

PSA has been used for several purposes related to prostate cancer: screening (testing in persons without symptoms or signs of disease), prediction of the course of disease, prediction of the stage of disease, and follow-up after treatment. The most controversial use of PSA measurements is in screening.

PSA has been used for several purposes related to prostate cancer: screening (testing in persons without symptoms or signs of disease), prediction of the course of disease, prediction of the stage of disease, and follow-up after treatment. The most controversial use of PSA measurements is in screening. Two large randomized trials have been published with long-term outcomes of prostate cancer screening. The US Prostate, Lung, Colorectal, and Ovarian Cancer Screening Trial showed no effect on cancer-specific or all-cause mortality after 10 years. The European Randomized Study of Screening for Prostate Cancer found that screening was associated with reduced
cancer-specific mortality in men aged 55 to 69 years after 9 years of follow-up; to prevent 1 cancer death, 1400 men would need to be screened and 48 treated.

Because of the side effects of diagnostic biopsy and complications of treatment of prostate cancer and the minimal, if any, survival benefit from prostate cancer screening, in 2012, the US Preventive Services Task Force recommended that men not be screened for prostate cancer. Guidelines for prostate cancer screening from other professional groups, including the American Urological Association (AUA) and the American College of Physicians (ACP), recommend individual decision making with information provided to the patient about both potential risks and benefits, and that screening might be reasonably offered to men between ages 50 (for the ACP) or 55 (for the AUA) and 69.

It should be noted that PSA is not highly sensitive for detecting cancer. It is estimated that only about 50% to 60% of those with localized and potentially curable cancer have increased PSA, and recent studies have found that many patients with less well-differentiated prostate cancers actually have PSA values as low as 1 ng/mL.

Limited evidence suggests that the rate of rise in PSA can predict more aggressive cancers. A review of published studies found that men with more rapid rises in PSA (a rise >0.35 ng/mL per year, 10 years before a definitive diagnosis, or a rise >2 ng/mL in the year before a definitive diagnosis) were far more likely to have recurrence after surgery and to die from cancer than those with more slowly rising PSA. In men who have decided to not have surgery, the rate of rise of PSA was also found to be predictive; if the PSA doubling time was less than 3 years, the likelihood of locally progressive disease was high, while it was very low for those whose PSA increased less than 2-fold over 10 years. More studies will be needed to confirm these findings and to determine whether this information can be useful in determining treatment.

PSA measurement is of some use in the initial staging of a patient with prostate cancer. In general, the higher the PSA, the less likely that cancer is localized to the prostate and the more likely that it has spread. Distant metastases are rare in persons with PSA <20 ng/mL, so performance of imaging studies of bone (the most common site of metastasis) for preoperative staging of cancer has little benefit in those with lower PSA values.

The most widely accepted use of PSA is to monitor patients after treatment. Since about 99% of prostate cancers produce PSA, and since PSA is made almost solely in the prostate, successful surgical removal of the gland (and cancer) should result in a serum PSA less than 0.1 ng/mL by 3 months after surgery. Failure of PSA to become undetectable indicates residual cancer that was not removed by surgery. With recurrence of cancer, PSA levels increase up to a year and a half before clinical evidence of recurrent cancer, allowing treatment of persons with rising PSA before their clinical condition deteriorates. With radiation therapy, PSA typically will fall to normal (usually to <1 ng/mL by 1 year after completion of radiation) with successful treatment, but will usually not be undetectable. Because prostate cancer responds to androgens, removal of the testes and the use of drugs that block androgen production are widely used to treat metastatic prostate cancer. The production of PSA is androgen dependent. Rarely, PSA levels will fall dramatically with androgen deprivation even though there is little or no change in the amount of tumor. In most cases, though, PSA is a reliable marker of tumor response to androgen deprivation as a treatment for prostate cancer.

TESTICULAR CANCER

Description

The 2 major categories of testicular tumors are germ cell tumors (which include seminomas and nonseminomatous germ cell tumors [NSGCT]) and sex cord or stromal tumors (mainly Leydig cell and Sertoli cell tumors). Seminomas and NSGCT comprise more than 90% of testicular cancers. Most persons with germ cell tumors have a mixture of histologic varieties. Testicular germ cell tumors have a peak incidence in 15- to 34-year-old males, and are the most common type of tumor found in men of that age group. Testicular cancer is most commonly identified by finding an enlarged testicle during a routine physical or by a man on self-examination. If an ultrasound examination confirms the presence of an intratesticular mass, surgery is usually performed quickly to remove the testicle, its adnexa, and a long segment of the spermatic cord.

More than 90% of testicular cancers arise from germ cell tumors. Germ cell tumors often produce substances that can be used as tumor markers to evaluate the patient for complete removal of the tumor, detect recurrent cancer, and monitor treatment for any residual or recurrent tumor.
(radical orchiectomy). The diagnosis of testicular cancer, like most other cancers, is made by histopathologic examination of the testicle.

**Diagnosis**

Germ cell tumors often produce substances that can be used as tumor markers to evaluate the patient for complete removal of the tumor, detect recurrent cancer, and monitor treatment for any residual or recurrent tumor. The 3 important serum tumor markers for testicular cancers are human chorionic gonadotropin (hCG), alpha-fetoprotein (AFP), and lactate dehydrogenase (LD). LD elevation, while present in about 50% of seminomas and 10% of NSGCT, is not specific, since damage to muscle, liver, cardiac, and other tissue damage can raise LD levels in the blood. Elevation of the LD-1 isoenzyme is characteristic of testicular tumors, but LD-1 is also elevated after myocardial infarction. Seminoma is associated with increased levels of hCG, but the increased levels are seen in only about 15% of seminoma cases. Pure seminomas do not produce AFP, but mixed tumors that contain predominantly seminomatous components may produce AFP. In NSGCT, approximately 85% to 90% of cases have at least 1 of the 3 tumor markers elevated. Yolk sac tumors produce AFP, a normal product of the fetal liver and yolk sac, in about 90% of cases. Choriocarcinoma, a malignant tumor resembling the placental cells, produces hCG in close to 100% of cases. As is generally true for circulating tumor markers, they are most useful for monitoring recurrence of disease or as a measure of response to therapy. Neither hCG nor AFP is useful in screening patients for testicular tumors, and they have a limited but helpful role in establishing the diagnosis. Higher levels of hCG and LD-1 at the time of diagnosis are associated with more aggressive cancers and, overall, a less favorable outcome, and are therefore included in staging classifications for testicular cancer cases. In order to determine whether a testicular tumor is associated with elevated tumor marker levels, it is recommended that baseline levels of these 3 markers be measured prior to surgery, since levels may fall quickly after surgery.

hCG, LD, and AFP are significantly affected by diseases in other organs. LD is found in all cells. Therefore, damage to any cell can cause increased LD. Since red blood cells contain LD, a sample collected for LD measurement in which there is red blood cell hemolysis will show an elevated LD, with much of the LD originating from red blood cells. This is also particularly problematic in the setting of chemotherapy, where transient LD increases occur from the cell damage expected from chemotherapy treatment. AFP is also produced by hepatocytes, as discussed in Chapter 16. Injury to the liver, as occurs with acute or chronic hepatitis, also commonly causes mild-to-moderate increases in AFP that can lead to suspicion of recurrent testicular carcinoma.

**MALE GONADAL DYSFUNCTION**

**Description**

While complete gonadal failure in men is rare (and is discussed more fully in Chapter 22), partial androgen deficiency is common with advancing age in men. This has also sometimes been referred to as “andropause,” and considered by some to be analogous to menopause, the age-related gonadal failure in women. There are a number of differences between age-related declines in gonadal function in men and women, however. While gonadal failure is inevitable in women, not all men develop low levels of testosterone. Menopause typically occurs between the mid-40s and mid-50s, whereas relative androgen deficiency develops over a much broader age range in men. Estrogen and progesterone levels fall to extremely low levels in women and are accompanied by high gonadotropin (FSH and LH) levels. However, partial androgen deficiency in men is associated with mildly decreased testosterone levels and is usually not associated with abnormally high gonadotropin levels. According to the Endocrine Society consensus guidelines based on testosterone levels in a reference population of healthy young men, only 7% of men in their 40s have low androgen levels. However, the figure rises to 30% of men in their 50s, almost half of those in their 60s, and to 90% of men in their 80s.
testosterone values seen in older men as abnormal might encourage inappropriate or unneeded supplemental androgen therapy.

As in women, routine use of hormone replacement in men is controversial. Androgens increase muscle and bone mass, and may protect against falls and bone fractures. Androgen deficiency can cause mood changes and sexual dysfunction, both of which may respond to androgen treatment. On the negative side, however, androgens are involved in the pathogenesis of both BPH and prostate cancer, may lead to a fall in sperm count, and cause undesirable changes in blood lipids, which may increase the risk of myocardial infarction and stroke. Limited data on safety and effectiveness of androgen replacement are available, and some level of efficacy that had been anticipated has not been shown in controlled trials. For example, administration of testosterone together with sildenafil was not better than sildenafil alone in improving erectile dysfunction in one study. Whereas treatment of hypogonadism in young men with primary gonadal failure is beneficial, clear clinical benefits of testosterone therapy in men aged 65 and above with age-related decreases in testosterone levels have not been demonstrated in randomized trials. Long-term effects of testosterone therapy on the risk of prostate-related and cardiovascular-related adverse events remain unknown.

Diagnosis
Laboratory testing for partial androgen deficiency generally begins with measurement of serum testosterone. Normal levels are often stated to be greater than 250 to 350 ng/dL. Androgen deficiency is unlikely to be present if the total testosterone is >400 ng/dL. A problem with evaluation of total testosterone levels is that changes in the level of testosterone-binding proteins are common. Free testosterone, not bound to proteins, contributes significantly more to the biological effects of testosterone than does protein-bound testosterone. However, it is widely believed that testosterone bound to albumin (about 40% of total) may contribute partially to the biological effects of testosterone. The major testosterone-binding protein, sex hormone-binding globulin (SHBG), is increased by androgen deficiency, but decreased by obesity, both common problems in older men. Ideally, free testosterone is quantitated, but some assays for measurement of free testosterone are unreliable. This has led to the use of tests to determine “bioavailable testosterone,” which are most helpful in those with testosterone levels between 200 and 400 ng/dL.

Transient decreases in testosterone and gonadotropin levels are commonly seen in persons who are acutely ill. Testing of gonadal function should be avoided in hospitalized individuals for that reason. Certain medications, as well as opiates and ethanol, can cause transient decreases as well. Testosterone secretion has a circadian rhythm, with higher levels in the morning, and lower concentrations in the afternoon and evening. The reference ranges for expected values of testosterone are generally based on morning samples. If treatment decisions are to be based on androgen concentrations, testosterone blood tests should be drawn in the morning, and fasting is not required. Since testosterone serum levels within an individual are variable, low concentrations should be confirmed by repeat testing before initiating therapy.

In young men with low testosterone, guidelines suggest measurement of LH. Generally, FSH follows LH and does not add additional information. It is expected that LH levels are usually within the reference range in age-related partial androgen deficiency. Very low levels of LH suggest a pituitary or hypothalamic problem, and require further evaluation of pituitary function, while high levels of LH suggest other causes of a low androgen level.

MALE INFERTILITY

Description
Infertility (defined as a failure to conceive after 1 year of unprotected intercourse) affects about 15% of couples attempting a pregnancy, and most experts agree that male infertility (alone or in combination with female infertility) accounts for about half of these cases. The causes of male infertility range from congenital absence of the vas deferens or incomplete spermatogenesis to subtle pathologies of sperm shape and function. In contrast, female infertility is usually caused by tubal blockage, uterine or endometrial abnormalities, or abnormal levels of reproductive hormones. Female infertility is relatively easily diagnosed by hormone assays, menstrual cycle

Infertility (defined as a failure to conceive after 1 year of unprotected intercourse) affects about 15% of couples attempting a pregnancy, and most experts agree that male infertility (alone or in combination with female infertility) accounts for about half of these cases.
analysis, and radiologic studies. The male partner in an infertile couple is often overlooked or incompletely evaluated, even though male factors may be a major contributing factor. Endocrine abnormalities (e.g., isolated androgen deficiency) are exceedingly rare (about 1%) among males of infertile couples. Since subtle sperm dysfunctions not obvious by microscopic semen analysis may preclude fertilization, a normal semen analysis (SA) is not necessarily predictive of fertility. In fact, a complete lack of sperm in semen (azoospermia) is the only highly predictive finding for infertility by SA.

Absence of spermatozoa in the semen may be caused by either failure of the testes to produce sperm (i.e., male sterility) or a blockage of the excurrent ducts of the male genital tract. The former is nonobstructive azoospermia (NOA), and the latter, obstructive azoospermia (OA). When azoospermia is discovered by SA, a medical history and physical examination by a qualified physician is recommended. Testicular biopsy may also be performed to differentiate NOA from OA. OA may be congenital or acquired. Vasectomy is usually an elective minor surgery leading to azoospermia for contraception, but the vas or epididymis also may become unknowingly blocked after a sexually transmitted infection. Azoospermia may persist after vasectomy reversal. Congenital bilateral absence of the vas deferens (CBAVD) is found in men carrying one of the many cystic fibrosis alleles, as well as in men with clinically apparent cystic fibrosis. In all these cases of OA, spermatozoa are almost always able to be retrieved from the testis by a urologic surgeon. Testicular sperm are not capable of fertilization except by intracytoplasmic sperm injection, in which individual sperm are microinjected into an oocyte in an in vitro fertilization (IVF) laboratory. In the case of a cystic fibrosis carrier, the partner should be checked to determine if she is also a carrier for cystic fibrosis so that the couple understands their risk to conceive a child.

Absence of the vasa deferentia may be determined by palpation on physical exam, and may be suggested by absence of fructose in the semen. Fructose is made exclusively in the seminal vesicles, and these glands contribute about 60% of the semen volume. Since they are embryonic outgrowths of the vasa deferentia, they are usually absent in men with CBAVD.

Two reasons for NOA are absence of germ cells in the testis (Sertoli-only syndrome) and failure of spermatogenesis (only mitotic cells or no late stages of sperm production). These conditions may be genetic, due to failure of primordial germ cells to migrate to the testis, or acquired through exposure to toxicants. In addition, microdeletions in the Y chromosome in specific regions are associated with NOA or severe oligozoospermia. Testosterone or androgen therapy (see above) for low testosterone or bodybuilding will often result in azoospermia or oligozoospermia due to inhibition of the hypothalamic–pituitary axis, decreased LH, and subsequent lowering of the high intratesticular:plasma ratio of testosterone required for sperm production. Men with testicular and other cancers may exhibit NOA or oligozoospermia. Conversely, men with NOA or oligozoospermia are at increased risk for later development of testicular cancer.

Spermatozoa may not be entirely missing in NOA. A few stem cells throughout the testis may be present, although a random biopsy may not detect any. In such cases, exceedingly low numbers of sperm may be present in the semen, possibly on a cyclical basis. Cryptozoospermia is the presence of very rare sperm in the semen. Often, high levels of FSH are associated with NOA, due to dysfunctional Sertoli cells and lack of the Sertoli hormone inhibin. However, high FSH has not proven to be a good indicator of the absolute absence of spermatogenesis. The surgical technique known as microsurgical testicular sperm extraction has proven to be useful in these cases. Under the surgical microscope, a few seminiferous tubules might be located that have complete spermatogenesis. Highly trained staff in the andrology or embryology laboratory are needed to identify and recover sperm from the testis in these cases.

In other cases of male infertility, sperm will be present in the semen. The human, unlike almost any other species, produces spermatozoa with numerous defects. “Normal” values for human SA are both surprisingly poorly established and highly variable from 1 ejaculate to another, and between different men. Although a typical ejaculate contains 200 to 300 million sperm, fertilization only takes 1, and at the time of fertilization there are only about a dozen sperm associated with the egg. If only 1% of sperm are functionally and structurally normal, then the typical ejaculate will contain about 2 to 3 million of these "good sperm." Apparently this is enough to help propagate the human population. SA helps identify men who have a few "good sperm," and diagnose specific sperm problems that may permit therapy or advanced reproductive techniques, or help guide decisions by the couple.
Diagnosis and Laboratory Test Interpretation

SA is the cornerstone of male infertility diagnosis, and should be performed early in the evaluation of the infertile couple. Collection of a semen sample should take place after 2 to 5 days of sexual abstinence. Longer abstinence is associated with lower motility and higher leukocyte counts, and shorter periods usually lead to lower volumes and sperm counts. A sterile plastic container, known not to be toxic to sperm, is required. Usually a sterile urine collection cup is satisfactory. If the sample is not collected in a special collection room near the lab, it should be transported in a tightly sealed collection cup in a sealed plastic bag, protected from light, heat, and cold. A temperature between room temperature and body temperature is adequate. Seminal fluid characteristics are measured after allowing semen to liquefy (due to the enzymatic action of PSA) for 15 to 30 minutes at 37°C or at room temperature. Analysis should be completed within 60 minutes after ejaculation. In vivo, sperm typically swim out of semen into the cervical mucus within a half hour. Semen may contain hepatitis, HIV, and other pathogens. Basic precautions for handling potentially infectious body fluids must be followed.

The main tests in SA are ejaculate volume, sperm count, sperm motility, sperm morphology, and leukocyte count. Aside from azoospermia, findings that may contribute to a couple’s infertility include low sperm concentration or total number of sperm (oligozoospermia), poor sperm motility (asthenozoospermia), very poor sperm morphology (teratozoospermia), or any combination of the 3. Additionally, a high number of neutrophils or macrophages in the semen (leukocytospermia) may affect sperm function by inducing oxidative stress through the generation of reactive oxygen species. Leukocytes are likely present in all semen samples. There is lack of consensus on the number that is considered abnormal, with authorities suggesting various cutoffs from 200,000 to 1 million per mL of semen.

A semen fructose analysis may be considered if there is unexpected azoospermia. Sperm viability is important to determine when motility is very low. Sperm agglutination and the presence of antisperm antibodies may indicate an immunologic basis for infertility. These highly specialized tests typically are performed in laboratories certified specifically for SA.

Interpretation of sperm morphology is controversial, largely because of a lack of supporting data relating sperm morphology to fertility. Very few human sperm are “perfect”; in fact, if at least 4% of sperm have normal morphology, then the specimen morphology is generally considered to be normal. The clinical significance of sperm morphology is best understood when most of the sperm have specific defects. The absence of acrosomes (the specialized structure at the tip of the sperm head) is associated with inability to fertilize eggs, and, sometimes, inability to activate oocytes to complete meiosis. Abnormal midpieces or tails may be associated with poor motility.

If SA is abnormal, it should be repeated after at least 1 month. SA parameters can vary substantially within an individual. Therefore, a single abnormal specimen should not be used to establish a diagnosis.

LEARNING OBJECTIVES

1. Understand the clinical utility of human chorionic gonadotropin (hCG) results in pregnancy, normal and ectopic, spontaneous abortion (miscarriage), and gestational trophoblastic disease.

2. Learn how to diagnose common complications of pregnancy, notably preeclampsia, eclampsia, HELLP syndrome, and fatty liver associated with pregnancy.

3. Understand the causes and the diagnosis of female infertility.

CHAPTER OUTLINE

Introduction 405
Normal Pregnancy 405
Maternal Serum Screening 407
Ectopic Pregnancy 408
Spontaneous Abortion (Miscarriage) and Recurrent Abortion 409

Gestational Trophoblastic Disease 410
Preeclampsia and Eclampsia 410
HELLP Syndrome 411
Fatty Liver of Pregnancy 411
Female Infertility 411

INTRODUCTION

Clinical laboratory testing is useful for the diagnosis and management of pregnancy and infertility, and such testing is reviewed in this chapter. Gestational diabetes mellitus (GDM) is discussed in Chapter 17, and hemolytic disease of the newborn (HDN) is found in Chapters 7 and 12. Female physiology and biochemistry including amenorrhea are discussed in Chapter 22. The female genital tract is also a common site for infections, which may be sexually transmitted, and it is a common site for tumors. The infections are presented in Chapter 5, and tumor descriptions are found in textbooks of anatomic pathology.

NORMAL PREGNANCY

Description

Normal pregnancy lasts approximately 40 weeks, as dated from the first day of the previous menstrual period, and is typically divided into 3 intervals or trimesters each lasting approximately 13 weeks. Approximately 5 days after fertilization, a blastocyst implants in the uterus. Trophoblast cells of the blastocyst invade the endometrium with chorionic villi leading to a placenta and the forming embryo surrounded by amniotic fluid. The placenta nourishes the embryo and produces hormones vital to pregnancy such as human chorionic gonadotropin (hCG), progesterone, estradiol, estriol, and estrone. The amniotic fluid protects the embryo and changes composition as the pregnancy progresses. The embryo undergoes rapid cell division, differentiation, and growth in the first trimester (0-13 weeks). By 10 weeks, most major structures are formed resulting in a
fetus. The second trimester (13–26 weeks) is associated with rapid fetal growth. Completion of maturation occurs in the third trimester (26–40 weeks) resulting in a term pregnancy between 37 and 42 weeks.

#### Diagnosis

Once pregnancy has been achieved, several laboratory tests are routinely performed to help ensure an optimal maternal and fetal outcome (Table 20–1). Most testing in pregnancy is performed on maternal serum because it is easy to obtain and provides minimal risk to the pregnancy, but maternal urine and amniotic fluid specimens may also be necessary. Of note, pregnancy has an effect on many laboratory tests, other than those used to diagnose and manage pregnancy, and these alterations should be considered when interpreting laboratory tests from pregnant women (Table 20–2).

</table>
hCG is one of the most commonly ordered tests in pregnancy. It is a heterodimer composed of 2 nonidentical nonconvalently bound glycoprotein subunits, alpha and beta, that is synthesized by the trophoblasts of the placenta. Only the intact molecule is biologically active. A single gene for the alpha subunit of all 4 glycoprotein hormones (thyroid-stimulating hormone [TSH], luteinizing hormone [LH], follicle-stimulating hormone [FSH], and hCG) is found on chromosome 6. hCG stimulates the LH receptor on the corpus luteum to produce progesterone that helps to prevent pregnancy loss.

Detectable amounts of hCG (>2-5 IU/L, depending on the assay) are present in serum 8 to 11 days after conception. Qualitative urine hCG tests are usually sufficient for screening, but the detection limits of qualitative tests range from 20 to 50 IU/L, limiting their use to the time following a missed menstrual period or greater than 14 days after conception. As opposed to qualitative testing, quantitative testing offers sensitivity as low as 2 to 5 IU/L and serial measurements may be helpful to reveal problems in a pregnancy. In normal pregnancies, hCG doubles every 1.5 to 2 days for the first 8 weeks (Table 20–1) and peaks around 100,000 to 500,000 IU/L.

Blood and urine contain many hCG variants, including free subunits, and hyperglycosylated and nicked forms. After 5 weeks of gestation the predominant hCG form in urine is the hCG beta core fragment. In addition, the hCG glycosylation changes as the pregnancy progresses. Quantitative hCG immunoassays typically measure total hCG beta concentrations using 2 antibodies against different regions of the beta subunit. False-negative hCG results can be seen in early pregnancy or when hCG concentrations are very high, causing a hook effect. False-positive results can be caused by heterophilic antibodies and by advanced maternal age (from pituitary hCG).

Other additional routine testing in pregnancy is performed to screen for common and/or treatable pregnancy complications such as gestational diabetes (see Chapter 17), hemolytic disease of the newborn (see Chapters 7 and 12), and infection (see Chapter 5) (Table 20–1).

**MATERNAL SERUM SCREENING**

**Description**

Maternal serum screening can be performed to identify individuals who need further diagnostic evaluation for fetal anomalies such as neural tube defects (NTDs), trisomy 21/Down syndrome, and trisomy 18. NTDs result from failure of fusion of the neural plate and failure of complete covering by the 27th day post conception. The extent and location of neural tissue exposed indicates the severity of the defect (ie, anencephaly, meningomyelocele, and encephalocele). The result of a NTD is a direct communication of the amniotic fluid with fetal plasma proteins, and release of alpha-fetoprotein (AFP) into amniotic fluid and maternal serum. Rates of NTDs have decreased due to the addition of folic acid to grain, as well as initiation of recommendations for folic acid supplementation prior to conception. Trisomy 21 or Down syndrome is caused by an extra copy of chromosome 21 and is the most frequent chromosomal disorder among live-born children (1/600 to 1/800 live births). Risk factors for Down syndrome include advanced maternal age, the birth of a previously affected child, and balanced parental structural rearrangement of chromosome 21. Affected children suffer from mental retardation, hypotonia, congenital heart defects, and a flat facial profile. The main phenotypic features of trisomy 18 include hypertonia, prominent occiput, small mouth, micrognathia, short sternum, and horseshoe kidney.

**Screening**

An additional discussion of maternal screening for Down syndrome is found in Chapter 7.

Screening for NTDs is done at 15 to 22 weeks gestation by measurement of serum AFP that is expressed as a multiple of the median population (MoM). MoMs greater than 2 or 2.5 are considered abnormal and should be followed up by high-resolution ultrasound or measurement of amniotic fluid AFP and acetylcholinesterase.

Sequential serum screening is performed to screen for trisomies and combines first- and second-trimester testing. First-trimester testing is performed between 10 and 14 weeks and includes measurement of hCG and pregnancy-associated plasma protein-A (PAPP-A) as well as an ultrasound measurement for infant nuchal translucency (NT). Specific training is required of operators for determination of NT. This procedure is highly operator dependent. Free beta hCG

Detectable amounts of hCG are present in serum 8 to 11 days after conception.

Maternal serum screening can be performed to identify individuals who need further diagnostic evaluation for fetal anomalies such as neural tube defects (NTDs), trisomy 21/Down syndrome, and trisomy 18.
testing is more accurate than intact hCG testing in the first trimester and is used instead of intact hCG for the first-trimester screen. PAPA-A is a protein produced by the placenta. Elevated hCG, decreased PAPP-A, and increased NT are seen in pregnancies affected by trisomy 21.

In the sequential screen, first-trimester screening is followed up with second-trimester screening at 15 to 22 weeks, with measurement of serum AFP, hCG, estriol, and inhibin A (ie, the quad screen). AFP is the most abundant serum protein in the fetal circulation. Maternal serum AFP is detectable at 10 weeks and peaks at 15 to 20 weeks. Estriol is the predominant estrogen of pregnancy and also the most difficult to measure because of low concentration and limited stability. Inhibin A, secreted by the ovaries and placenta, is a glycoprotein that inhibits FSH. Concentrations of individual analytes from the first- and second-trimester screens and NT measurements are combined into a risk assessment algorithm that adjusts for gestational age, maternal weight, number of fetuses, and presence or absence of diabetes mellitus. The most frequent causes of abnormal results include incorrect dating, the presence of twins, and fetal demise. For this reason, an ultrasound confirming gestational age is the first line of testing in a patient with apparently increased risk. Fetal karyotyping is necessary to confirm chromosomal abnormalities.

Second trimester-only testing can be done and should utilize the quad screen. Elevated hCG, increased inhibin A, decreased estriol, and decreased AFP are seen in pregnancies affected by trisomy 21, while all 4 analytes in the quad screen are decreased in pregnancies affected by trisomy 18. Patients at risk should undergo further diagnostic evaluation as described with sequential screen.

Recently, new methods have been developed for trisomy 21 screening using circulating fetal DNA. These methods utilize “massively parallel genomic sequencing” (MPGS). DNA fragments are isolated from a sample of maternal blood, which contains a mixture of maternal DNA and infant DNA. The DNA fragments are amplified and then sequenced. The number of sequences that originate from a particular chromosome is counted and tabulated for each chromosome. If a fetus has an extra chromosome, then the percentage of DNA fragments from that chromosome is higher than expected. These tests have been shown to have excellent detection rates (~99%) with very low false-positive rates (~0.2%). Currently, MPGS is only validated for the detection of Down syndrome and not other fetal aneuploidies such as trisomy 18 or trisomy 13. The test does have the capability of detecting these disorders and, if they are detected, the results are reported. However, because the test has not been thoroughly investigated for detecting trisomy 18 or trisomy 13, a negative result does not rule out their presence. Also, the test does not detect open NTDs (eg, spina bifida), for which screening usually involves biochemical (not genetic) screening tests.

The American College of Obstetricians and Gynecologists (ACOG) cautions that these tests are screening tests, not diagnostic tests. They also recommend that DNA-based screening tests be performed only on women who are at increased risk of having a fetus with aneuploidy, including women with: maternal age 35 years or older at delivery, fetal ultrasound findings suggesting aneuploidy, a previous aneuploid pregnancy, or abnormal biochemical screening test results.

ECTOPIC PREGNANCY

Description
Ectopic pregnancies arise if the fertilized egg implants in a location other than the body of the uterus, primarily in the fallopian tube. Of all reported pregnancies, 1.3% to 2% are extrauterine. The nonuterine location of implantation prevents normal development. Despite increased awareness and improved diagnostic modalities, such as serial hCG and transvaginal ultrasound, ectopic pregnancies are the leading cause of maternal death in the first trimester. Risk factors for ectopic pregnancy include tubal damage from either infection or disease, smoking, infertility, and previous miscarriage.

Diagnosis
Three classic symptoms of an ectopic pregnancy include lower abdominal pain, vaginal bleeding, and an adnexal mass. However, only 25% of women with ectopic pregnancy have these symptoms at the time of presentation, making laboratory testing and transvaginal ultrasound examination essential for diagnosis and management.
essential for diagnosis and management. In ectopic pregnancies, abnormal concentrations of hCG are present (Table 20–3). hCG concentrations in ectopic pregnancy range from undetectable to 200,000 IU/L, depending on the size and viability of the trophoblastic tissue. Therefore, the absolute concentration of hCG is not very useful in the diagnosis of ectopic pregnancy. Many utilize a so-called discriminatory zone of hCG in which a fetus should be visible when hCG concentrations are >2000 IU/L. However, recent studies suggest that the discriminatory zone is not very reliable and can lead to misdiagnosis. Instead serial testing reveals rates of hCG increase as slow as 35% over 2 days in ectopic pregnancy. Medical therapy with methotrexate or surgery is required to prevent rupture and significant hemorrhage.

SPONTANEOUS ABORTION (MISCARRIAGE) AND RECURRENT ABORTION

**Description**

Spontaneous abortion or miscarriage refers to a pregnancy that ends spontaneously before the fetus has reached a viable gestational age. The most common complication of early pregnancy is spontaneous abortion, and it occurs in approximately 10% to 20% of all recognized pregnancies under 20 weeks gestation. The percentage increases if unrecognized or subclinical pregnancies are included. Risk factors include advanced maternal age, previous miscarriage, smoking, and alcohol or drug consumption. Chromosomal abnormalities account for approximately 50% of all miscarriages.

Recurrent spontaneous abortion is defined as 3 or more consecutive intrauterine pregnancy losses prior to 20 to 24 weeks of gestation. It affects up to 1% to 5% of fertile couples. Primary aborters have had no live births, while secondary aborters were able to achieve at least 1 successful pregnancy. Assisted reproduction technologies are much less effective in women with recurrent fetal losses compared with those with infertility.

**Diagnosis**

Women experiencing a miscarriage may present with a history of amenorrhea, vaginal bleeding, and lower abdominal pain. Serial measurements of hCG concentration in conjunction with physical examination and ultrasonography can be helpful in the diagnosis of spontaneous abortion. Decreasing hCG concentrations are consistent with a spontaneous abortion or nonviable pregnancy. Patients with a confirmed miscarriage can be managed expectantly, medically with misoprostol, or surgically. Following treatment, hCG concentrations can be monitored until the
concentration is undetectable to confirm complete expulsion of products of conception. It may take 30 to 60 days before serum hCG concentrations are undetectable. The etiology of recurrent loss is often unclear, but can include genetic, anatomic, hormonal, thrombotic, placental, infectious, environmental, or psychological causes. Immunological factors may also play a role. Following a detailed history, physical examination, and radiological studies, additional laboratory tests may be helpful in determining the cause of the recurrent loss (Table 20–4). Of all the etiologic factors, only parental genetics has been shown to be a definitive cause of recurrent loss. Although uterine abnormalities, antiphospholipid antibodies, the Factor V Leiden mutation, and other thrombotic risk factors (see Chapter 11) are definitely associated with recurrent loss, there is not sufficient proof of a causative role.

**GESTATIONAL TROPHOBLASTIC DISEASE**

**Description**

Gestational trophoblastic diseases are a spectrum of disease processes originating from the placenta that include hydatidiform mole, invasive mole, and choriocarcinoma. Malignant gestational trophoblastic diseases have the potential for local invasion and metastasis.

Hydatidiform moles are the most common and occur in 1 of 600 therapeutic abortions and 1 of 1100 pregnancies. Approximately 20% of patients will be treated for malignant sequelae after evacuation of a hydatidiform mole. Gestational choriocarcinoma occurs in approximately 1 in 30,000 pregnancies.

**Diagnosis**

Gestational trophoblastic diseases are usually diagnosed early in pregnancy. Patients present with abnormal bleeding and vague complaints. Ultrasound and serum hCG testing are used to make the diagnosis of gestational trophoblastic diseases. Ultrasound findings include the absence of a fetal heartbeat. hCG testing reveals greatly elevated hCG concentrations (Table 20–3). Dilation and evacuation (D&E) procedures are performed to treat patients. Serial hCG measurements should be performed after treatment to ensure complete removal of tumor and monitoring of disease for recurrence. Chemotherapy may be necessary in cases of malignant transformation.

**PREECLAMPSIA AND ECLAMPSIA**

**Description**

Preeclampsia is a multisystem disorder of unknown etiology, and it is a major cause of morbidity and mortality in pregnancy. Preeclampsia is diagnosed by the occurrence of new hypertension and proteinuria in the second half of pregnancy.
have accompanying seizures, occurs less frequently. Eclampsia is more serious and carries a higher morbidity and mortality rate. Treatment includes controlling symptoms until delivery.

**Diagnosis**

Preeclampsia is diagnosed by the occurrence of new hypertension and proteinuria in the second half of pregnancy. Hypertension in pregnancy is defined as a persistent systolic blood pressure ≥140 mm Hg and/or a diastolic blood pressure ≥90 mm Hg. Proteinuria in preeclampsia is >300 mg/L protein in a 24-hour urine specimen or >1 g/L protein in a single urine specimen (Table 20–3). It should be demonstrated that seizures associated with eclampsia are not explained by a neurological disorder such as epilepsy.

### HELLP SYNDROME

**Description**

The HELLP syndrome involves hemolysis, elevated liver enzymes, and a low platelet count. The syndrome can occur during pregnancy, typically between weeks 27 and 36, or in association with preeclampsia; it can also occur postpartum.

**Diagnosis**

The HELLP syndrome and preeclampsia have similar clinical presentations. A low platelet count and abnormal liver enzymes are important to make a diagnosis of the HELLP syndrome (Table 20–3). The hemolysis in the HELLP syndrome is microangiopathic, and this results in schistocytes on the peripheral blood smear, an elevated indirect bilirubin, and an increased lactate dehydrogenase (LD) activity.

### FATTY LIVER OF PREGNANCY

**Description**

Approximately 1 in 13,000 pregnancies is affected by fatty liver of pregnancy. First pregnancies and multiple gestation pregnancies are at a higher risk. Symptoms, which are nonspecific and include nausea and vomiting, right upper quadrant pain, and lethargy, typically begin around the 36th week of gestation. Liver biopsies show accumulation of microvesicular fat, which may be caused by a defect in mitochondrial beta oxidation of fatty acids or a long-chain 3-hydroxyacyl CoA dehydrogenase deficiency. Treatment involves immediate delivery to prevent fulminant hepatic failure requiring liver transplantation. Recurrence in subsequent pregnancies is rare.

**Diagnosis**

The diagnosis is made using both clinical symptoms and laboratory results. Although liver biopsy is virtually diagnostic in the setting of pregnancy, it is rarely necessary. The laboratory test abnormalities include mild elevations in liver enzymes (AST > ALT), increased bilirubin, hypoglycemia, and hyperuricemia (Table 20–3). Abnormal coagulation test results, as indicated by a prolonged prothrombin time, a prolonged partial thromboplastin time, and a low fibrinogen, are found in acute fatty liver of pregnancy, but not in HELLP syndrome, and this helps differentiate the 2 conditions.

### FEMALE INFERTILITY

**Description**

Infertility is defined as the inability to achieve a successful pregnancy following 1 year of unprotected intercourse. It is estimated that 15% to 25% of couples will experience an episode of infertility. Couples with primary infertility have had no previous successful pregnancies. Couples with secondary infertility had prior pregnancies, but are currently unable to conceive. Both primary and secondary infertility have common causes, most often problems with the hypothalamic–pituitary–gonadal axis.
Midluteal progesterone concentrations greater than 10 ng/mL indicate normal ovulation while concentrations less than 10 ng/mL suggest anovulation, inadequate luteal phase progesterone production, or inappropriate timing of sample collection. Serum concentrations of FSH and estradiol can be measured on day 3 of the menstrual cycle to indicate ovarian reserve.

**Diagnosis**

Factors contributing to female infertility include ovarian, hormonal, tubal, cervical, uterine, psychosocial, iatrogenic, and immunological factors. Ovulatory disorders, such as hypergonadotropic hypogonadism and hypogonadotropic hypogonadism, are the most common and are described in more detail in Chapter 22. Other disorders such as polycystic ovarian disease, obesity, thyroid dysfunction, androgen excess, and liver dysfunction can also contribute. Following a detailed history and physical examination, laboratory evaluation of female infertility is performed. Midluteal progesterone concentrations greater than 10 ng/mL indicate normal ovulation while concentrations less than 10 ng/mL suggest anovulation, inadequate luteal phase progesterone production, or inappropriate timing of sample collection. Serum concentrations of FSH and estradiol can be measured on day 3 of the menstrual cycle to indicate ovarian reserve. TSH and prolactin (PRL) can be used to assess for thyroid or pituitary dysfunction.

**REFERENCES**

INTRODUCTION

This chapter focuses on laboratory testing relevant to breast cancer. Infections of the breast are included in Chapter 5.

BREAST CANCER

Description

Cancers of the breast constitute a major cause of mortality in women of Western countries. In the United States, the lifetime probability that a woman will develop breast cancer is 1 in 8. Breast cancer accounts for 29% of new cancer cases and 14% of cancer deaths in American women. About 1% of breast cancers occur in males. The risk of developing breast cancer is influenced by several factors. These factors include increased age, family history of breast cancer (especially in a first-degree relative), hormonal factors (early age at menarche, older age of menopause, older age at first full-term pregnancy, fewer number of pregnancies, and use of hormone replacement therapy), clinical factors (high breast tissue density and benign breast diseases associated with atypical hyperplasia), obesity, and alcohol consumption. Since 1990, the mortality rate associated with female breast cancer has decreased in the United States, a decline that has been attributed to both therapeutic advances and early detection.

For localized breast cancer, primary treatment typically consists of either breast-conserving surgery and radiation or mastectomy. Most patients with invasive breast cancer subsequently receive systemic adjuvant chemotherapy and/or hormone therapy, both of which have been shown to reduce systemic recurrence and breast cancer-related mortality. However, the fact that some patients who lack lymph node involvement are cured by the combination of surgery and radiotherapy suggests that adjuvant treatment may not be necessary in all cases.
Therefore, to rationally administer adjuvant therapy to patients with local disease, several prognostic factors are considered to assess the risk for recurrence. These prognostic factors include tumor size, axillary node involvement, histological type, cytological grade, lymphatic and vascular invasion, and certain biomarkers associated with breast cancer.

While adjuvant therapy improves patient outcomes, 25% to 30% of women with lymph node-negative and at least 50% to 60% of women with node-positive disease develop recurrent or metastatic disease. Metastatic breast cancer is currently regarded as incurable. Therapeutic options for metastatic disease include chemotherapy, hormone therapy, and molecularly targeted therapies. In the context of metastatic disease, information gained from serial monitoring of tumor markers detected in the serum may contribute to decisions to continue or terminate a particular treatment.

**LABORATORY TESTING**

**Tissue-based Biomarkers in Breast Cancer**

Assessment of biomarkers in tissue obtained from the patient’s breast tumor is routinely performed to obtain prognostic information and to guide therapy.

**Estrogen Receptor (ER) and Progesterone Receptor (PR)**

ER and PR are intracellular receptors that bind to lipid-soluble steroid hormones that diffuse into target cells. Following ligand binding, 2 receptor subunits dimerize to form a single, functional DNA-binding unit that binds to specific DNA target sequences to induce transcription of target genes. There are 2 different forms of the ER, termed ER-α and ER-β, which are encoded by separate genes. Clinical assays assess ER-α, the classical form of the receptor. PR has 2 isoforms that differ in molecular weight but are encoded by a single gene.

Measurement of the ER and PR status of the tumor is recommended in all patients with breast cancer. ER expression is present in approximately 70% of breast cancers, is associated with a favorable prognosis, and suggests that the growth of the tumor may be estrogen-dependent. The primary purpose of determining ER and PR status in breast cancers is to identify those patients, in both the adjuvant and metastatic settings, who are likely to respond to endocrine treatments. These treatments act by either preventing the formation of estrogen from its precursors or blocking estrogen from binding to its receptors. Endocrine treatments include tamoxifen, ovarian ablation (surgical or chemical), aromatase inhibitors (anastrozole, letrozole, and exemestane), and irreversible ER inhibitors (eg, fulvestrant). In patients with ER-positive tumors, 5 years of adjuvant treatment with tamoxifen significantly reduces annual death rates from breast cancer, while in patients with ER-negative tumors, tamoxifen shows little effect on recurrence or death, and it does not significantly modify the effects of polychemotherapy.

ER/PR status is routinely assessed by immunohistochemistry (IHC) in the clinical setting. IHC evaluates the percentage of cells with nuclear ER/PR. The intensity of staining is also recorded as a measure of assay quality. The use of validated antibodies is required, and a positive control (ie, a control tissue with tumor cells known to express the respective receptor) must be examined in parallel. A tumor is scored as positive for either ER or PR if ≥1% of tumor cell nuclei are immunoreactive. A tumor is scored as negative for ER or PR if <1% of tumor cell nuclei are immunoreactive in the presence of demonstrable staining in adjacent normal breast epithelial cells, which serves as an internal positive control. If tumor cells are not found to be immunoreactive and the specimen lacks an appropriately stained internal control, the tumor is scored as uninterpretable for ER or PR. For optimal results, breast resection specimens should be fixed within 1 hour. Fixation should be performed in 10% neutral buffered formalin for at least 6 hours and for not more than 72 hours in order to preserve ER and PR epitope recognition and thus avoid false-negative results.

**HER2**

HER2 (also known as ERBB2 and NEU) is a proto-oncogene located at chromosome 17q11 that is a member of the epidermal growth factor receptor (EGFR) family. Like other EGFR family
members, HER2 is a transmembrane receptor with cytoplasmic tyrosine kinase activity. Dimerization of the receptor leads to phosphorylation of a variety of substrates, resulting in the activation of intracellular signaling pathways important for cell proliferation and survival.

While normal cells contain 2 copies of the HER2 gene (1 copy on each chromosome 17), in approximately 10% to 25% of breast cancers HER2 gene copy number is increased at least 2-fold relative to the number of copies of chromosome 17, a phenomenon termed gene amplification. Gene amplification results in overexpression of the HER2 protein at the cell surface, which in turn promotes tumor cell proliferation and survival. Tumors that overexpress HER2 behave more aggressively than those lacking overexpression, and they are associated with poorer clinical outcomes.

Assessment of HER2 status of the tumor is recommended in all patients with invasive breast cancer. The primary purpose of HER2 testing is to identify those patients with early or advanced breast cancer who are eligible for treatment with trastuzumab, a recombinant monoclonal antibody that recognizes HER2. Although its exact mechanism of action remains to be fully elucidated, trastuzumab has been shown in both in vitro assays and animal studies to inhibit proliferation of human tumor cells that overexpress HER2. In patients with HER2-positive early stage breast cancer, the addition of trastuzumab to adjuvant chemotherapy significantly improves disease-free and overall survival. Additionally, in patients with HER2-positive metastatic breast cancer, the addition of trastuzumab to adjuvant chemotherapy significantly increases the time until disease progression. Because a small percentage of patients treated with trastuzumab develop cardiotoxicity, the elimination of false-positive HER2 results is important so that patients are not exposed to this risk unnecessarily.

HER2 status is routinely assessed in formalin-fixed tissues by either fluorescence in situ hybridization (FISH) or IHC. FISH assesses HER2 status at the DNA level. A fluorescent-labeled nucleic acid probe that recognizes the HER2 gene on chromosome 17 is hybridized on tissue sections, and the average number of HER2 signals per nucleus is determined in areas of invasive tumor. In some assay systems, an additional probe that recognizes the centromeric region of chromosome 17 (CEP17) (and which is labeled with a different fluorophore) is included to allow the ratio of the average number of copies of HER2:CEP17 (the “FISH ratio”) to be calculated. Tumors with intermediate results are considered equivocal for gene amplification; in these cases, IHC for HER2 protein may be performed to resolve HER2 status. Chromogenic in situ hybridization (CISH) may be performed as an alternative to FISH. In CISH, the HER2 probe is visualized by an immunoperoxidase reaction. This enables CISH results to be scored using a conventional light microscope rather than the fluorescence microscope that is required for FISH.

In contrast to the FISH assay, IHC assesses HER2 status at the protein level. The level of HER2 protein expression is scored on a semiquantitative scale. Tumors with 3+ protein expression are scored as positive for HER2 protein expression, while tumors with 0 or 1+ protein expression are scored as negative. Tumors with intermediate staining patterns (eg, cases showing complete membrane staining that is weak in intensity) are considered equivocal; in these cases, FISH may be performed to resolve HER2 status.

**Multigene Prognostic Assays**

Recently, clinical assays that utilize expression information gathered across a panel of genes have been developed to predict recurrence risk and guide adjuvant chemotherapy decisions in patients with early stage breast cancer. Several assays, which examine different sets of genes, are currently available. Two of the more widely validated testing platforms involve examination of 21 and 70 genes, respectively. Depending on the particular testing platform, fresh frozen tissue or formalin-fixed, paraffin-embedded tissue may be required. While methods used to quantify gene expression vary by platform, 1 approach involves using the enzyme reverse transcriptase to convert messenger RNA into complementary cDNA; the resulting cDNA then serves as a template for assays such as quantitative polymerase chain reaction or microarray gene expression profiling. While the role for these multigene prognostic assays in the routine clinical management of patients with breast cancer remains to be fully established, several of these assays have been validated in retrospective studies, and their utilities are now being examined in prospective studies.
Serum-based Biomarkers in Breast Cancer

Serum-based tumor markers may be useful in the identification and management of patients with breast cancer. The ideal breast cancer marker would be both specific for breast cancer and sufficiently sensitive for screening purposes. Unfortunately, no marker identified to date meets these criteria. However, some markers may have utility in evaluating the progression of disease after initial therapy and for monitoring subsequent treatment.

When considering the use of serum tumor markers, several points should be kept in mind: 1) none of the currently available markers is elevated in all patients with breast cancer, even in the setting of advanced disease, so that a normal tumor marker level does not exclude a malignancy; 2) these markers are most sensitive for detecting metastatic disease and have little value in the diagnosis of local or regional recurrences; 3) the magnitude of change in marker levels that correlates with disease progression or regression has not been firmly established; 4) tumor marker levels may paradoxically rise after initiation of chemotherapy, a phenomenon attributed to therapy-mediated apoptosis or necrosis of tumor cells; 5) tumor marker levels may be increased in the setting of certain benign diseases.

CA 15-3 and CA 27.29

CA 15-3 and CA 27.29 represent different but overlapping epitopes of the MUC1 protein, a large, complex glycoprotein expressed at the luminal surface of glandular epithelial cells. In malignant cells, MUC1 may be overexpressed, and increased amounts of MUC1 may be shed into the circulation. MUC1 levels in serum may be assessed by immunoassays employing distinct monoclonal antibodies that recognize either the CA 15-3 or CA 27.29 epitopes. Results obtained from assays assessing CA 15-3 and CA 27.29 are highly correlated. Importantly, CA 15-3 elevations have been shown to occur in other malignancies and, to a lesser extent, in nonneoplastic disease. These pathologic conditions include adenocarcinomas of the colon, lung, ovary, and pancreas, as well as chronic hepatitis, cirrhosis, sarcoidosis, tuberculosis, and systemic lupus erythematosus.

In early stage breast cancer, elevated CA 15-3 levels are associated with a worse prognosis. However, because CA 15-3 and CA 27.29 show fairly low sensitivity for detection of early disease, the role of these markers in the management of early stage breast cancer remains unclear. Measurement of either CA 15-3 or CA 27.29 is therefore not recommended for screening, diagnosis, or staging of breast cancer. After primary and/or adjuvant therapy, increases in CA 15-3 or CA 27.29 can predict recurrence several months before other testing modalities or the development of symptoms. However, because prospective, randomized clinical trials have yet to demonstrate if such early detection of occult or asymptomatic metastases impacts disease-free or overall survival, the routine use of CA 15-3 and CA 27.29 for this application is not currently recommended. In patients with metastatic disease who are undergoing active therapy, CA 15-3 or CA 27.29 testing may be used in conjunction with history, physical exam, and diagnostic imaging to monitor the response to treatment. While the use of CA 15-3 or CA 27.29 alone to monitor response to treatment is not recommended, in the absence of readily measurable disease, an increasing CA 15-3 or CA 27.29 may be used nonetheless to identify treatment failure. In most clinical trials to date, a significant alteration in CA 15-3 has been defined as a concentration change of at least 25%.

Carcinoembryonic Antigen (CEA)

CEA is a cell-surface glycoprotein involved in cell adhesion that is normally expressed in the developing fetus. CEA levels in the blood decrease to very low levels after birth, although levels may be elevated slightly in smokers. CEA expression may be elevated in several types of cancer, including cancers of the breast, colon, pancreas, lung, and ovary, because of antigen shedding into the circulation. CEA may also be elevated in nonneoplastic diseases, including inflammatory bowel disease, pancreatitis, and liver disease. CEA is detected by immunoassay.

In early stage breast cancer, elevated CEA levels are associated with a worse prognosis. CEA is not recommended for screening, diagnosis, staging, or routine surveillance of breast cancer patients after primary therapy. Like CA 15-3 and CA 27.29, CEA testing may be used in conjunction with history, physical exam, and diagnostic imaging to monitor the response to treatment in
patients with metastatic disease who are undergoing active therapy. However, CEA should not be used alone for this purpose. Compared with CA 15-3, CEA is generally a less sensitive marker for breast cancer. However, in some patients with breast cancer, elevations of CEA may occur in the setting of normal CA 15-3 or CA 27.29 levels.

**HEREDITARY BREAST AND OVARIAN CANCER SYNDROME**

**Description**

While most cases of breast cancer are caused by acquired somatic mutations, approximately 5% to 10% of breast cancer cases are attributed to a germline mutation in a highly penetrant cancer predisposition gene. A large proportion of these hereditary cases are associated with mutations in 2 genes, *BRCA1* and *BRCA2*. Mutations in *BRCA1* and *BRCA2* cause the hereditary breast and ovarian cancer syndrome, an autosomal dominant disorder in which the risk of both breast and ovarian cancer is significantly increased compared with the general population. *BRCA1* and *BRCA2*, which are located at chromosome 17q21 and 13q12, respectively, are tumor suppressor genes that play essential roles in the repair of double-stranded DNA breaks and thus in the maintenance of genome stability. Accordingly, in tumors from individuals with hereditary breast and ovarian cancer syndrome, the wild-type *BRCA1* or *BRCA2* allele is deleted, consistent with a tumor suppressor function for *BRCA1* and *BRCA2*.

A woman's risk for harboring either a *BRCA1* or *BRCA2* mutation is increased by certain factors related to her personal and family medical history. Personal factors include: 1) early onset breast cancer (ie, diagnosis before 50 years of age); 2) bilateral or multifocal breast cancers; and 3) a history of both breast and ovarian cancer. Factors from the family history include: 1) breast cancer or breast and ovarian cancer in a pattern consistent with autosomal dominant transmission; and 2) breast cancer in a male relative.

Hereditary breast and ovarian cancer syndrome shows incomplete penetrance. Among women with either a *BRCA1* or *BRCA2* mutation, the lifetime risk of developing breast cancer is 60% to 80%. The lifetime risk of developing ovarian cancer is 15% to 60% for women with *BRCA1* mutations and 10% to 27% for women with *BRCA2* mutations. Mutations in *BRCA1* and *BRCA2* also increase the risk of male breast cancer. Individuals with hereditary breast and ovarian cancer syndrome are also at risk for other tumors, including melanoma and cancers of the prostate (in males) and pancreas.

Determination of *BRCA1* and *BRCA2* mutation status is an important clinical assessment, as the identification of a deleterious mutation may alter clinical management. Interventions available to *BRCA1* and *BRCA2* mutation carriers include intensive screening, chemoprevention, prophylactic mastectomy, and prophylactic oophorectomy. Prophylactic oophorectomy, which reduces the risk of breast cancer as well as ovarian cancer, is recommended for all mutation carriers at the completion of childbearing.

**Determination of *BRCA1* and *BRCA2* Mutations**

Genetic testing for *BRCA1* and *BRCA2* mutations should be offered to individuals with a personal or family history suspicious for hereditary breast and ovarian cancer syndrome, and to women at risk because of a family member known to harbor a deleterious mutation in 1 of these genes. It is critical that testing be offered in the setting of appropriate genetic counseling, so that individuals are provided appropriate information regarding the risks, benefits, and limitations of genetic testing. Such counseling should also include consideration of how the results of such testing might affect other family members.

Study of kindreds with hereditary breast and ovarian cancer syndrome has identified hundreds of different deleterious mutations in the *BRCA1* and *BRCA2* genes. Most consist of frameshift or nonsense mutations, which are predicted to result in a loss of function of the encoded gene product. Due to the large number of different mutations described, genetic testing to assess for most of these involves examination of the DNA sequence of the entire coding region of each gene. Additional molecular testing may also be employed to assess for certain large genomic rearrangements that cannot be detected by routine DNA sequencing. In cases

Approximately 5% to 10% of breast cancer cases are attributed to a germline mutation in a highly penetrant cancer predisposition gene. A large proportion of these hereditary cases are associated with mutations in 2 genes, *BRCA1* and *BRCA2*. Genetic testing for *BRCA1* and *BRCA2* mutations should be offered to individuals with a personal or family history suspicious for hereditary breast and ovarian cancer syndrome, and to women at risk because of a family member known to harbor a deleterious mutation in 1 of these genes.
where a known deleterious mutation has already been identified in a family member, targeted mutation analysis is performed to specifically assess for the familial mutation.

When possible, genetic testing should be performed on an individual who has been diagnosed with breast or ovarian cancer because this strategy provides the most information for other members of the family. Genetic testing can lead to 4 possible outcomes: a true-positive result, a true-negative result, an uninformative result, and a variant of uncertain significance. A true-positive result occurs when a deleterious mutation known to be associated with increased cancer risk is identified; such a result confirms the diagnosis of hereditary breast and ovarian cancer syndrome. A true-negative result occurs only when the tested individual is found to lack a specific deleterious mutation already known to run in the family; a true-negative result thus reduces the tested individual’s risk of developing breast and/or ovarian cancer to that of general population. An uninformative result occurs when a mutation is not identified in an individual from a family in which a deleterious mutation has not yet been identified; an uninformative result does not exclude the possibility of a BRCA1 or BRCA2 mutation that cannot be detected by current testing methodologies, nor does it exclude the possibility of a mutation in another cancer susceptibility gene. Genetic variants of uncertain significance are typically missense variants of unknown functional significance or intronic variants not predicted to disrupt mRNA processing; individuals harboring variants of unknown significance may still be at increased risk for cancer, and their medical management should be based on the known family history. In all cases, posttest genetic counseling should be performed to ensure that individuals fully comprehend the implications of their testing results.

**OTHER HIGH-PENETRANCE CANCER PREDISPOSITION GENES**

In addition to BRCA1 and BRCA2, highly penetrant forms of hereditary breast cancer have also been linked to mutations in the tumor suppressor genes TP53, PTEN (phosphatase tensin homolog), and STK11. While mutations in these genes comprise a smaller proportion of hereditary breast cancer cases than BRCA1 and BRCA2, identification of these mutations similarly has profound implications for clinical management and for genetic risks of family members. Genetic testing for mutations in these genes is conducted using molecular approaches similar to those used for BRCA1 and BRCA2 and can also lead to the same 4 possible test outcomes described above. Genetic testing for these mutations should be offered in the setting of appropriate genetic counseling to at-risk family members of an individual with a known deleterious mutation and to individuals with personal or family histories suspicious for these particular syndromes, which are described in detailed below.

**Li-Fraumeni Syndrome**

Germline mutations in TP53 cause Li-Fraumeni syndrome, a rare autosomal dominant condition associated with the development of a variety of tumor types throughout life, including in childhood. TP53, located at chromosome 17p13, encodes the p53 protein, which plays key roles in DNA repair, cell cycle control, and the initiation of apoptosis. In addition to breast cancer, tumors associated with Li-Fraumeni syndrome include osteosarcomas, soft tissue sarcomas, brain tumors, leukemias, and adrenocortical carcinomas. In families with Li-Fraumeni syndrome, breast cancer is common and may account for one third of all cancers.

**Cowden Syndrome**

Germline mutations in PTEN cause Cowden syndrome, a rare autosomal dominant condition characterized by an increased risk of certain cancers and the development of multiple skin and mucosal hamartomas (focal malformations that resemble neoplasms but result from faulty development of the tissue). PTEN, located at chromosome 10q23, encodes a phosphatase that downregulates the phosphatidylinositol-3-kinase (PI3K) signal transduction pathway, thereby contributing to the regulation of cell growth. The spectrum of cancers seen in Cowden syndrome includes thyroid cancer, uterine cancer, renal cell cancer, and breast cancer. Females with Cowden syndrome have a 25% to 50% lifetime risk of developing breast cancer.
**Peutz-Jeghers Syndrome**

Germline mutations in *STK11* cause Peutz-Jeghers syndrome, a rare autosomal dominant condition characterized by gastrointestinal polyps and mucocutaneous pigmentation. *STK11*, located at chromosome 19p13, encodes serine/threonine-protein kinase 11 and functions to regulate cell polarity, energy utilization, and apoptosis. Individuals with Peutz-Jeghers syndrome are at increased risk for the development of a variety of cancers, including colorectal, gastric, pancreatic, ovarian, and breast. The lifetime risk of breast cancer reported for females with Peutz-Jeghers syndrome has been estimated at 30% to 50%.

LEARNING OBJECTIVES

1. Learn the physiology and biochemistry of the relevant hormones and other important mediators.
2. Understand the laboratory tests used in the diagnosis of the more commonly encountered disorders.
3. Identify the clinical disorders associated with each of the endocrine glands and the role of specific laboratory tests in their diagnosis.

INTRODUCTION

This chapter on endocrine disorders is divided into separate discussions of each of the endocrine glands. Each section begins with an overview of the physiology and biochemistry of the relevant hormones. In addition, because of the large number of (often complex) laboratory tests in endocrinology, each section has a brief description of the laboratory tests most frequently used to diagnose the disorders in that disease group. Tests for which either serum or plasma is an acceptable specimen for analysis are noted as serum tests. Tests specifically requiring plasma are indicated by inclusion of the word “plasma” before the test name. As with all other chapters, each disorder is presented with a description of the disease and information useful in establishing a diagnosis. 

Figure 22–1 shows a general approach to the patient with endocrine disease.

THYROID

Physiology and Biochemistry

Production of thyroid hormones is regulated by the hypothalamic–pituitary–thyroid axis (Figure 22–2). Thyrotropin-releasing hormone (TRH) is produced in the hypothalamus and induces thyroid-stimulating hormone (TSH or thyrotropin) production in the anterior pituitary. TSH, in turn, stimulates thyroid hormone production and release by the thyroid gland. TSH production is inversely related to plasma thyroxine (T₄) and triiodothyronine (T₃) concentrations. The 2 primary hormones synthesized and secreted by the thyroid gland are T₄ and, in lesser quantities, T₃ (Figure 22–3). They are transported by plasma proteins—notably thyroid-binding globulin (TBG), transthyretin, and albumin—to various tissue sites where T₃ is deiodinated to the active form, T₂, and the inactive form known as reverse T₃ (rT₃). Thyroid hormones act through nuclear hormone receptors that are transcription factors for numerous genes. These genes regulate a number of critical physiologic functions in development and metabolism.

Laboratory Tests

TSH

A “generational” classification has been applied for TSH immunoassays based on the assay sensitivity. Third-generation assays can accurately measure TSH as low as 0.01 mU/L. This allows the physician to distinguish mildly subnormal TSH values from the low values of overt hyperthyroid patients. The third-generation tests are also useful for evaluating the effectiveness of the thyroid

---

**Figure 22-1** An approach to the patient with an endocrinologic disorder.
hormone replacement in hypothyroid patients. Third-generation assays are essential for monitoring TSH suppression therapy in patients with a TSH-responsive thyroid tumor.

The relationship between TSH and the thyroid hormones, particularly free $T_4$, is an inverse log-linear one, such that very small changes in free $T_4$ result in large changes in TSH. Thus, TSH is the most sensitive first-line screening test for suspected thyroid abnormalities. If the TSH is within the normal reference range, no further testing is performed. If the TSH is outside of the reference range, a free $T_4$ is obtained.
Total Thyroid Hormone Measurements

Assays are available for both total T₄ and total T₃ measurements. These assays are quite specific and suffer little interference. However, transient changes in serum thyroid hormone-binding protein concentrations may affect total T₄ and T₃ concentrations. Therefore, an assessment for free T₄ (see below) is usually more helpful in evaluating thyroid function. The concentration of T₄ in the blood is usually 100 to 200 times greater than the T₃ level. In hyperthyroidism, total T₄ and T₃ concentrations correlate in all but a small subset of patients who have an elevation only in T₃. For that reason, T₃ should be measured in the serum of patients clinically suspected to be hyperthyroid and who have normal concentrations of serum T₄. Measurement of T₃ concentrations has limited clinical utility in assessment of hypothyroidism. Significant decreases in total T₃ are seen in euthyroid sick syndrome (ETS).

Free Thyroid Hormones and Thyroid Hormone-binding Capacity

"Direct" free thyroid hormone assays, without the need for a preliminary step to separate free hormones from hormones bound to protein carriers, are available for measurement of free T₄ and free T₃. Only a small fraction of T₄ (≤0.1%) circulates unbound to proteins, and this has made the accurate quantitation of free T₄ analytically difficult. Free T₄ is a better indicator of thyroid status than total T₄ because, as noted above, the total T₄ is altered by changes in the amounts of TBG, albumin, and other thyroid hormone-binding proteins. About 0.3% of T₃ circulates as free T₃. In general, free T₃ concentrations correlate well with total T₃, but as with T₄, the concentrations of thyroid hormone-binding proteins influence the total T₃ level.

Although the free T₄ index offers an approximation of free T₄, this measure is largely obsolete due to improvements in the free hormone assays. The free T₄ index is calculated by multiplying the total T₄ by the measure of available hormone-binding sites on TBG in an assay known as the percent T₃ uptake. Because of the dependence on the amount of TBG, the free T₄ index and the T₃ uptake are affected by changes in the amount of thyroid-binding proteins induced by a variety of stimuli.

Reverse Triiodothyronine

Under acute stress or in illness, there is a shift in the T₄ deiodination in favor of the inactive rT₃ form rather than the active T₃. Numerous immunoassays are available for the measurement of rT₃, using antisera that do not cross-react significantly with T₄ or T₃. rT₃ is markedly increased in ETS syndrome (see below), but its measurement is rarely required for this diagnosis because its increase is proportional to the decrease in T₃.

Antithyroid Antibodies

Antithyroid antibodies are present in approximately 15% of the general population and are the most common cause of thyroid disease in iodine-replete societies. They are also present in selected autoimmune diseases not usually associated with thyroid dysfunction. Descriptions of 3 types of antithyroid antibodies follow:

- **Antimicrosomal/antithyroid peroxidase antibodies (anti-TPO)**—These antibodies are directed against a protein component of thyroid microsomes, the enzyme TPO. They are present in almost all patients with Hashimoto thyroiditis, in about 85% of patients with Graves disease (both discussed below), and in some patients with type 1 insulin-dependent diabetes mellitus, celiac disease, and Addison disease. An elevated titer of anti-TPO antibodies in the context of clinical symptoms of thyroid dysfunction and abnormal TSH and free T₄ results is diagnostic for autoimmune thyroid disease. The presence of TPO antibodies before or during pregnancy is a good predictor of those women who will develop postpartum thyroid disease (discussed below). Normal concentrations are not well established because the antibodies may be found in healthy people (up to 12% of the population), and the reference range depends on the method used to perform the test.

- **Antithyroglobulin antibodies**—These are also called colloidal antibodies. They are present in more than 85% of patients with Hashimoto thyroiditis and in more than 30% of patients with Graves disease. Like anti-TPO, antithyroglobulin antibodies also may be found in other autoimmune diseases. In iodine-sufficient areas, the antithyroglobulin antibody test is
used less often, in favor of anti-TPO. However, in patients with suspected iodine deficiency, antithyroglobulin antibody is a better indicator of autoimmune thyroid disease.

- **TSH receptor antibodies**—These are a diverse group of immunoglobulins that bind to TSH receptors and influence their action. They are found in most patients with Graves disease and in patients with selected other autoimmune disorders involving the thyroid. The biological functions of these antibodies vary from thyroid stimulation to thyroid inhibition (by blocking stimulation induced by TSH). Antibodies referred to as thyroid-stimulating immunoglobulins are present in 95% of patients with untreated Graves disease. In vitro bioassays can assess the ability of stimulatory antibodies to induce functional responses in cultured cells by measuring cyclic adenosine monophosphate increases or adenylate cyclase activity. Assays are available that measure the capability of the inhibitory antibodies, called thyrotropin-binding inhibitory immunoglobulins, to block the binding of labeled TSH to its receptors.

### Radioactive Iodine Uptake and Thyroid Scans

The radioactive iodine uptake and thyroid scan measurements involve the in vivo administration of radioactive iodine. Accumulated radioactivity in the thyroid is measured at intervals within 24 hours using a gamma scintillation counter. A nuclear imaging scan that examines the anatomic distribution of radioactive iodine uptake within the thyroid gland also may be obtained. Radioactive iodine uptake studies may be helpful when the diagnosis is in question and in differentiating between possible causes of hyperthyroidism.

### Thyroglobulin

Thyroglobulin is stored in the follicular colloid of the thyroid as a prohormone. Thyroglobulin measurements are used to monitor treatment in thyroid cancer. Persistent serum thyroglobulin after thyroidectomy is evidence of incomplete ablation or metastatic thyroid cancer. Thyroglobulin concentrations should always be assessed in the context of an antithyroglobulin antibody test because these autoantibodies can cause false-positive or -negative thyroglobulin results.

### Calcitonin

Calcitonin is a polypeptide hormone produced by the thyroidal C cells, whose primary function is in regulating calcium homeostasis. It is elevated in patients with C-cell hyperplasia and medullary thyroid carcinoma (MTC). Calcitonin measurements are used to determine when to perform prophylactic thyroidectomy on patients with familial MTC. In addition, it is used to assess prognosis and monitor recurrence of MTC post thyroidectomy.

### Fine Needle Aspiration (FNA) Cytology

FNA is the procedure of choice to collect a specimen for microscopic review to distinguish benign from malignant thyroid nodules. The sensitivity of thyroid FNA for detection of thyroid cancer and other disorders varies from 70% to 97%. It depends greatly on the quality of the specimens and the experience of the cytopathologist. Thyroglobulin can also be measured in lymph node FNA aspirates to diagnose and monitor thyroid cancer.

### Hyperthyroidism Overview and Associated Disorders

#### Description and Diagnosis

Hyperthyroidism, also known as thyrotoxicosis, is a collection of disorders associated with excess thyroid hormone (Table 22–1). There are 4 main causes of hyperthyroidism: 1) overstimulation of the thyroid (elevated TSH, human chorionic gonadotropin [hCG], and/or TSH receptor autoantibodies [TRAbs]); 2) genetic mutations leading to increased synthesis and secretion of thyroid hormone (germline, sporadic, or tumor induced); 3) release of excess hormone from the thyroid (inflammation, infection, injury); 4) extrathyroidal sources of thyroid hormone (ectopic thyroid tissue or exogenous hormone). Patients with hyperthyroidism demonstrate a spectrum of hypermetabolic features, including nervousness, palpitations, muscle weakness, increased appetite, diarrhea, heat intolerance, warm skin, weight loss, and perspiration. Affected patients also
may have exophthalmos, emotional changes, menstrual changes, and a fine tremor of the hands. In the presence of a clinical history and physical examination consistent with hyperthyroidism, a diagnosis of hyperthyroidism (but not necessarily its cause) can be established by the demonstration of a low TSH level and a high free T4. In uncommon situations, only the total T3 level is elevated and the serum free T4 is normal (T3 thyrotoxicosis). To determine the etiology of the hyperthyroidism, additional testing is usually necessary. Graves disease, toxic multinodular goiter (TMNG), and toxic adenoma account for the vast majority (>95%) of cases of hyperthyroidism. It should be noted that diffuse or focal enlargement of the thyroid gland, also known as goiter, can be associated with hyperfunction, normal function, and hypofunction of the gland.

**Thyroid Storm**

Thyroid storm is a relatively uncommon, but life-threatening manifestation of hyperthyroidism caused by excess circulation of thyroid hormones. Symptoms of thyroid storm are similar, but much more severe than traditional hyperthyroidism, including a markedly high fever of 105°F to 106°F, tachycardia, hypertension, and neurological and gastrointestinal abnormalities. Thyroid storm is precipitated by acute illnesses such as sepsis, diabetic ketoacidosis, and preeclampsia, as well as surgical or other diagnostic or therapeutic actions such as radioactive iodine use, anesthesia, excessive thyroid hormone ingestion, or thyroid palpation. Thyroid storm is associated with a high fatality rate if not identified early. The diagnosis is based on the presence of clinical signs and symptoms of severe hyperthyroidism in the context of a precipitating cause. In addition, marked elevations in free and total T4 are common in thyroid storm. Total T4 is unreliable in this setting because concomitant nonthyroidal illness (NTI) may cause T4 to decrease significantly.

**Graves Disease**

Graves disease is a relatively common hyperthyroid disorder occurring more frequently in women. It is an autoimmune disease caused by TSH receptor autoantibodies that bind to and stimulate TSH receptors resulting in autonomous production of thyroid hormone.
antibodies (TRAbs) that bind to and stimulate TSH receptors resulting in autonomous production of thyroid hormone. While many patients have the classic signs and symptoms of thyrotoxicosis, in elderly patients with Graves disease, apathy, muscle weakness, and cardiovascular abnormalities occur more often than hypermetabolic symptoms.

Laboratory tests show undetectable TSH and increased free T4. In some cases, the T3 is elevated and the T4 is normal. The differential diagnosis includes TMNG, toxic adenoma, painless and subacute thyroiditis, ectopic thyroid tissue, and anxiety states (see below for descriptions). Detection of TRAbs along with the results from radioactive iodine uptake and nuclear thyroid scans are helpful in distinguishing among these possibilities. There is usually increased radioactive iodine uptake in Graves disease. The pattern on imaging is diffuse.

**Toxic Multinodular Goiter**
The cause of hyperthyroidism in patients with TMNG is an apparent functional autonomy of certain areas within the thyroid gland. The disorder is seen more commonly in elderly patients. The degree of hyperthyroidism is generally less severe than that found in Graves disease. Cardiovascular symptoms are prominent, such as arrhythmias, atrial fibrillation, or congestive heart failure, with weakness and wasting.

Laboratory tests usually show low or undetectable TSH and normal or elevated free T4 and T3 concentrations and no evidence of thyroid autoantibodies. Patients with TMNG will have normal to high radioactive iodine uptake, and the thyroid scan shows iodine localized to active nodules.

**Toxic Adenoma**
Thyroid adenomas that secrete thyroid hormones and cause hyperthyroidism are known as toxic adenomas. Thyroid hormone synthesis by a toxic adenoma is usually independent of TSH regulation, and it results in suppression of TSH secretion. These tumors can usually be distinguished from TMNG and Graves disease by a radioactive iodine uptake study and thyroid scan because there is localized uptake in the adenoma and little or no uptake in surrounding thyroid tissue.

**Thyroiditis**

**Subacute Thyroiditis.** Subacute thyroiditis is produced by a viral infection that alters thyroid function. This disease usually lasts for months, with thyroid function eventually returning to normal. The patient often has an associated upper respiratory infection, fever, and local pain mimicking a sore throat or an earache.

Patients in the early stage of this disease may have hyperthyroidism, with elevated T3 and T4 concentrations and a low TSH. Laboratory findings also often include a high erythrocyte sedimentation rate and little to no radioactive iodine uptake. If the disease progresses and the thyroid hormones are depleted, the patient develops hypothyroidism with low T3 and T4 concentrations and an elevated TSH.

**Postpartum Thyroiditis.** Postpartum thyroid disease is a transient inflammatory process that has an onset of 1 to 6 months postpartum. Although the etiology is unclear, it is thought to be caused by a rebound in the immune system in response to the general state of immunosuppression that occurs during pregnancy. This disease can present as either hyperthyroidism or hypothyroidism. The typical disease course begins with a period of hyperthyroidism with elevated free T3, reduced TSH, and little to no radioactive iodine uptake for 3 to 6 months. This is followed by a 3- to 6-month period of hypothyroidism associated with reduced concentrations of free T4 and elevated TSH that completely resolves after 1 year. Approximately 20% of women with postpartum hypothyroidism develop permanent disease, requiring lifelong treatment and monitoring. The presence of anti-TPO antibodies prior to and during pregnancy is associated with an increased risk for postpartum thyroiditis.

**Painless Thyroiditis.** Painless thyroiditis may be induced by numerous drugs including lithium, interferon, and in a small portion of patients on amiodarone therapy. Further, some patients with chronic thyroiditis have a transient painless thyrotoxicosis, of unclear etiology.

Typically, free T3 and T4 concentrations are elevated with a low TSH. Patients have a markedly depressed radioactive iodine uptake. Painless thyroiditis can be distinguished clinically from subacute thyroiditis because an elevated erythrocyte sedimentation rate and local pain in the
region of the thyroid are more consistent with subacute thyroiditis. A definitive diagnosis can be made by microscopic review of cells obtained by aspiration or biopsy. Thyroglobulin measurements can differentiate among patients with chronic thyroiditis from those with thyrotoxicosis caused by surreptitious thyroid hormone intake.

**Hypothyroidism Overview and Associated Disorders**

**Description and Diagnosis**

When hypothyroidism occurs during development and in infancy, it results in a condition known as cretinism, which is marked by retardation of physical and intellectual growth. In 95% of cases, hypothyroidism originates in the thyroid gland itself. If a patient has an increased serum TSH and a decreased free T₄—together with appropriate clinical symptoms—a diagnosis of hypothyroidism is confirmed (Table 22–1). In asymptomatic patients, increased TSH, accompanied by a normal free T₄, is known as subclinical hypothyroidism and may be indicative of early stages of primary hypothyroidism. High titers of anti-TPO antibodies suggest Hashimoto thyroiditis (see below) or postpartum thyroid dysfunction in a postpartum woman. While in the United States, autoimmunity is the main cause of hypothyroidism, iodine deficiency is the primary cause worldwide.

Hypothyroidism also may be a result of inadequate stimulation of the thyroid by TSH. This is known as secondary hypothyroidism. A subnormal free T₄ with a decreased or inappropriately normal TSH is suggestive of secondary hypothyroidism from decreased TSH production or production of a biologically inactive form of TSH in the pituitary. It is usually accompanied by other pituitary hormone deficiencies, and it is much less common than primary hypothyroidism.

Clinical pictures of hypothyroidism differ, depending on the age. Congenital hypothyroidism is characterized by low production of thyroid hormones and can result in growth and intellectual delay if untreated. In the United States, all states screen for congenital hypothyroidism by testing for elevated TSH or a combination of elevated TSH and decreased free T₄. Significant changes in thyroid function occur in the neonatal period and throughout childhood. Therefore, TSH and free T₄ concentrations should be assessed using age-specific reference intervals. In particular, T₄ is typically elevated in newborns. In adults, hypothyroidism can have an insidious onset, especially in the elderly. Symptoms are usually nonspecific in the early stage and then progress to more definitive characteristics of hypothyroidism with dry hair, dry skin, periorbital puffiness, dull expression, large tongue, and enlarged heart. If untreated, myxedema coma with respiratory failure may occur. Treatment involves hormone replacement.

**Hashimoto Thyroiditis**

Hashimoto thyroiditis is a common chronic inflammatory disease of the thyroid that accounts for as many as 90% of all cases of hypothyroidism. Autoimmune factors are thought to be the cause. Hashimoto thyroiditis is often associated with other autoimmune diseases such as Sjögren syndrome and pernicious anemia.

Patients with Hashimoto thyroiditis carry anti-TPO and antithyroglobulin antibodies. Firm thyroid enlargement and goiter is characteristic, but atrophy is also seen. Patients typically have an increased TSH and may have a normal free T₄ and an elevated radioactive iodine uptake in the early stage of the disease. Over time, serum T₄ declines first, followed by a decline in T₃ as hypothyroid symptoms become predominant.

**Postablative Hypothyroidism**

Postablative hypothyroidism is a relatively common cause of hypothyroidism in adults. Thyroid ablation occurs with total or subtotal thyroidectomy, or following treatment with radioactive iodine for hyperthyroidism.

A history of ablative therapy along with an elevated TSH and a low free T₄ concentration indicates that ablation has produced a hypothyroid state.

**Infantile Hypothyroidism**

Severe hypothyroidism in infancy is known as cretinism and, as previously noted, is characterized by irreversible mental retardation and growth impairment unless treated promptly.
The appearance of symptoms depends on the severity of the disorder. However, even severe hypothyroidism is not usually apparent at birth. Early diagnosis and treatment with thyroid hormone prevents the manifestations of the disease. Elevated TSH and a low T4 in a newborn or young infant are indicative of infantile hypothyroidism.

**Pregnancy-related Thyroid Disease**

Normal pregnancy is associated with a number of physiologic changes in thyroid function resulting in differences in “normal” laboratory values for thyroid function tests. The increase in estrogen stimulates hepatic synthesis of TBG, resulting in a net increase in total T3 and total T4 by about 1.5-fold. Significant homology exists between hCG, the pregnancy-associated glycoprotein hormone (see Chapter 20), and TSH. Because of this, hCG can directly stimulate the thyroid to produce thyroid hormone. Excess production of thyroid hormone signals a downregulation of TSH secretion. In the first trimester of pregnancy, increasing hCG concentrations are directly mirrored by decreasing TSH concentrations, which return to low normal in the second and third trimesters. Thus, TSH measurements in pregnancy should be considered in the context of gestational age and a reduced upper limit of normal. Many laboratories now report TSH with trimester-specific reference intervals.

Thyroid dysfunction during pregnancy can result in increased risks for the mother and fetus. Hypothyroidism during pregnancy is associated with an increased risk of miscarriage or preterm delivery and impaired neurological development in the fetus. Although controversial, it is recommended to screen all high-risk and symptomatic pregnant women for hypothyroidism by measuring TSH. Hyperthyroidism in pregnancy is associated with an increased risk of spontaneous abortion, preterm delivery, preeclampsia, and thyroid anomalies in the newborn. A subnormal TSH test result should be followed with free T4 testing. An elevated free T4 with the presence of autoantibodies confirms the diagnosis of hyperthyroidism in pregnancy. In mothers with confirmed thyroid disease, fetal thyroid function can be evaluated with ultrasound and amniotic fluid testing for TSH, free T4, and total T4. Normal reference intervals are instrument-specific for amniotic fluid thyroid function tests.

**Euthyroid Sick Syndrome**

**Description**

It is estimated that 40% of emergency department patients have euthyroid sick syndrome (ETS) at presentation. Stress, trauma, and illness can alter thyroid hormone production, transport, and metabolism, and thereby TSH levels, because of disruption of the normal feedback relationship between TSH and T3 and T4. This condition with altered thyroid hormone levels and no intrinsic disorder of the thyroid gland is called ETS or NTI, of which there are several variants.

**Diagnosis**

There is no consensus in the literature regarding the diagnosis and also therapy of ETS. The cause of ETS is different from patient to patient and is dependent on the history and any endocrinologic diagnosis. In moderately ill patients with ETS, serum T4 concentrations are within the reference range, while serum T3 is decreased and rT3 is increased. Serum TSH concentrations are typically normal to low (except for a transient increase that may occur during recovery). However, it is not recommended to measure TSH in hospitalized patients unless there is a strong suspicion for thyroid disease. In seriously ill patients, ETS presents with low-normal T3 and significantly reduced total T4 concentrations. Serum rT3 is increased because of slow thyroid hormone clearance and greater than normal conversion of T4 to rT3 rather than to T3. An elevated rT3 in the appropriate clinical setting, with appropriately suggestive laboratory test results, points to ETS syndrome.

**Thyroid Tumors**

**Description**

Masses or “nodules” in the thyroid may be associated with normal function, hyperfunction, or hypofunction, and for that reason, they are considered apart from hyperthyroidism and
hypothyroidism. In fact, some studies suggest that 25% to 40% of the population have thyroid nodules. Most solitary masses detected with physical examination are the dominant nodule in a multinodular goiter, a cyst, or an asymmetric enlargement of the gland. Benign thyroid adenomas account for most of the neoplastic nodules. The initial evaluation for a thyroid nodule is to measure TSH and perform a thyroid ultrasound. If the TSH is suppressed, a nuclear scan can be performed. Hyperfunctioning nodules appear as “hot nodules” by nuclear scan because they take up radioactive iodine while uptake is suppressed in the remainder of the gland. A nonfunctional (cold) nodule carries an increased risk of malignancy and should be followed with ultrasound-guided FNA or biopsy. The morphologic variants of thyroid cancer, diagnosed with histopathologic review of a biopsy specimen or aspirate (in order of frequency), are papillary carcinoma, follicular carcinoma, medullary thyroid carcinoma, and anaplastic carcinoma.

**Diagnosis**

The diagnosis is established by histopathologic review of a specimen obtained with FNA or biopsy. The accuracy of the diagnosis is increased with the use of guided ultrasound examination for sample collection. Treatment and risk of recurrence of thyroid neoplasms are assessed by periodic measurement of tumor markers, including thyroglobulin for papillary and follicular carcinomas, and calcitonin for MTC.

**ADRENAL CORTEX**

**Physiology and Biochemistry**

The adrenal cortex secretes many steroid hormones that have a wide variety of physiologic effects. The hormones can be grouped into 3 major categories: glucocorticoids, mineralocorticoids, and sex steroids that include androgens, progestogens, and estrogens. The glucocorticoids and mineralocorticoids are collectively known as corticosteroids. Steroid hormones are synthesized from cholesterol in the adrenal glands and in the gonads. They are transported in the blood bound to carrier proteins, such as albumin and hormone-binding globulins, or as free hormone. Steroids may be modified with glucuronate or sulfate to increase their water solubility and permit excretion via the kidneys or the gastrointestinal tract. The percentage of steroid hormone that is bound to protein varies with the hormone affinity for carrier proteins and ranges from 60% to nearly 100%. Quantitatively, the glucocorticoids and mineralocorticoids are the most important group of hormones produced by the adrenal cortex. The major corticosteroids are cortisol (a glucocorticoid) and aldosterone (a mineralocorticoid). The synthesis and metabolism of the steroid hormones are illustrated in Figure 22–4. The liver is the main site for conjugation of steroid hormones, and the kidney excretes approximately 90% of the conjugated steroids. Glucocorticoids alter carbohydrate metabolism by increasing gluconeogenesis and decreasing glucose utilization. Additional effects include the inhibition of amino acid uptake and protein synthesis in peripheral tissues. Mineralocorticoids promote sodium conservation and potassium loss and thereby considerably influence the retention or loss of fluid. Among the naturally occurring mineralocorticoids, aldosterone has the highest mineralocorticoid activity followed by deoxycorticosterone and corticosterone.

Secretion of adrenal glucocorticoids and adrenal androgens is regulated by corticotropin (ACTH) that is secreted by the pituitary gland (Figure 22–5). ACTH also plays a minor role in aldosterone and mineralocorticoid production. Their synthesis is primarily controlled by a different pathway known as the renin–angiotensin system. The hypothalamic–pituitary–adrenal (HPA) axis begins with the episodic release of corticotropin-releasing hormone (CRH) from the hypothalamus. CRH stimulates the episodic release of ACTH from the pituitary. ACTH then stimulates the adrenal cortex to produce cortisol in a diurnal or circadian manner. Cortisol concentrations are highest in the early morning between 4 and 8 AM and about 25% lower in the late evening. Physical and mental stress can elevate cortisol concentrations and blunt the circadian rhythm. ACTH release is under negative feedback control from the cortisol fraction not bound to proteins. Two adrenal sex steroids dehydroepiandrosterone (DHEA) and androstenedione are also stimulated by ACTH as well as other hormones including insulin-like growth factor-1 and gonadal steroids. Adrenal androgen production reaches a peak in the second decade, with a rise during late childhood. It gradually decreases and reaches a low level in the elderly.
CHAPTER 22 The Endocrine System

**FIGURE 22–4** The synthesis and metabolism of steroid hormones of the adrenal cortex.

**FIGURE 22–5** Hypothalamic–pituitary–adrenal cortex interactions. [+] Stimulation; [−] inhibition.
As shown in Figure 22–6, aldosterone secretion is primarily controlled by the renin–angiotensin system. Renin is an enzyme synthesized and stored in cells of the juxtaglomerular afferent arterioles of the renal glomeruli. The circulating renin hydrolyzes angiotensinogen to produce angiotensin I, which is rapidly converted to angiotensin II by angiotensin-converting enzyme. Angiotensin II then stimulates the cells of the adrenal cortex to produce aldosterone. Angiotensin II is also a potent vasoconstrictor. The primary stimuli for renin release are decreased perfusion of the kidney and a negative sodium balance.

**Laboratory Tests**

The functional status of the adrenal cortex can be evaluated by measuring the circulating concentrations of components of the HPA axis and the renin–angiotensin system. In addition to measurement of the plasma, serum, or urinary concentrations of these compounds, dynamic stimulation and suppression tests are valuable in identifying certain abnormalities.

**Cortisol**

Because the secretion of cortisol is diurnal and pulsatile, a single, random serum cortisol measurement is not usually diagnostic for adrenal dysfunction. The 24-hour urinary excretion of cortisol is a reliable gauge of excess cortisol secretion by the adrenal cortex. The 24-hour urinary excretion of cortisol, an index of plasma-free cortisol during that 24-hour time frame, is a reliable gauge of excess cortisol secretion by the adrenal cortex. This is because taking an average urine cortisol concentration over 24 hours eliminates the need to account for diurnal variation as in a single serum collection. Urinary free cortisol (UFC) measurements should not be used in patients with
renal impairment. Late-night salivary cortisol is also a measure of free cortisol since the binding protein does not cross into saliva. Salivary cortisol concentrations correlate well with serum concentrations and are not influenced by changes in cortisol-binding protein concentrations. Measurement of late-night salivary cortisol is an acceptable screening method for hypercortisolism.

**Low-dose Dexamethasone Suppression Tests**

Dexamethasone is a synthetic glucocorticoid more potent than cortisol that, when given orally or IV, suppresses ACTH and CRH secretion. It can be administered as 1 mg at midnight in an overnight dexamethasone suppression test, or in a 2-day low-dose dexamethasone suppression test (LDDST) by giving the patient 0.5 mg every 6 hours for 8 doses. If the dexamethasone is effective, it will suppress ACTH secretion and, thereby, suppress cortisol production. Patients with Cushing disease normally do not show suppression of cortisol synthesis after either dexamethasone administration for the LDDST or dexamethasone in the overnight suppression test.

**ACTH**

In patients with an abnormal dexamethasone suppression test, ACTH measurements are important to determine whether Cushing syndrome is ACTH-dependent. The optimum time of day for determination of plasma ACTH concentration in patients with suspected Cushing syndrome is between midnight and 2 AM when the plasma-circulating concentrations of ACTH and cortisol are at their lowest point. At this time, the ability to detect an abnormality in ACTH secretion is the greatest. In patients with suspected adrenal insufficiency, ACTH should be measured in the morning during its peak. Suppressed morning ACTH may indicate excess adrenal cortisol secretion.

**ACTH Stimulation Test**

The ACTH stimulation test is the most useful test in diagnosis of adrenal insufficiency. It assesses the secretory response of the adrenal cortex to an ACTH-like stimulus. A 250-mg dose of an ACTH analog, Cortrosyn or cosyntropin, is administered IV or IM and serum cortisol is measured at 0, 30, and 60 minutes after injection. Normally, ACTH analogs will stimulate production of cortisol to concentrations >20 mg/dL. Lack of rise in cortisol after ACTH stimulation may indicate primary and secondary adrenal insufficiency.

**CRH Stimulation Test**

CRH can be administered intravenously to determine the response of the pituitary to stimulation by hypothalamic hormone. The CRH stimulation test can be used to determine the source of adrenal insufficiency in patients with an abnormal ACTH stimulation test. Synthetic CRH is administered IV, and then ACTH and cortisol are measured at 0, 30, 60, 90, and 120 minutes after injection. Normal patients will respond to CRH by stimulating ACTH and cortisol production. Patients with primary adrenal insufficiency will have elevated ACTH, but no cortisol production, while patients with secondary disease will have both low ACTH and cortisol.

**Aldosterone**

The most important test to establish a diagnosis of hyperaldosteronism or hypoaldosteronism is plasma aldosterone. Aldosterone can be measured in the plasma as the unmodified hormone, and in the urine as the 18-glucuronide conjugated metabolite of aldosterone. Screening for primary aldosteronism should include the determination of the ratio of plasma aldosterone concentration (PAC)/plasma renin activity (PRA), that is, the aldosterone to renin ratio (ARR). Aldosterone and renin concentrations are affected by numerous conditions and medication. Therefore, it is recommended that testing be performed under the following conditions: patients with normal potassium concentrations, patients with normal salt intake, patients removed from drugs that affect the ARR, and midmorning collection in patients who have been ambulatory for at least 2 hours.

**Renin**

PRA is assayed by measuring its ability to convert angiotensinogen to angiotensin I, which is then quantitated by an immunoassay. When primary aldosteronism is present, often because of
either resistant or severe hypertension, the ARR will be elevated. Renin mass can also be assessed directly by immunoassay, to determine the direct renin concentration (DRC). Although the ARR can be calculated using DRC or PRA, fewer studies have investigated the utility of DRC. Renin specimens should not be stored refrigerated or on ice prior to analysis as cold temperatures promote secretion of prorenin, which falsely elevates results. See the section “Aldosterone” for recommended testing conditions.

**Steroid Measurements to Identify Enzyme Deficiencies in Congenital Adrenal Hyperplasia**

Congenital adrenal hyperplasia (CAH) represents a spectrum of diseases resulting from enzyme deficiencies that impair normal hormone synthesis in the adrenal cortex. The decrease in cortisol production in most forms of CAH leads to an overproduction and shunting into the androgen synthesis pathway. These disorders are described in the section “Alterations in the Synthesis of Glucocorticoids, Mineralocorticoids, and Sex Steroids: Congenital Adrenal Hyperplasia.” The assays used to identify the specific enzyme deficiencies include measurement of 17-hydroxyprogesterone (17-OHP), either unstimulated or after ACTH stimulation, 17-hydroxypregnenolone after ACTH stimulation, deoxycorticosterone, 11-deoxycortisol, and several androgens (androstenedione, DHEA, and testosterone). DNA-based tests also can be used to identify certain gene mutations that result in enzyme deficiencies found in CAH.

**Hyperfunction Involving Glucocorticoids With or Without Mineralocorticoids: Cushing Syndrome**

**Description**

Cushing syndrome is a disorder of excess cortisol production, which is more commonly ACTH-dependent than ACTH-independent. The early clinical features of Cushing syndrome are hypertension and weight gain. Truncal obesity with a round face, often known as a “moon facies,” and an accumulation of fat in the posterior neck and regions of the back close to the neck, known as a “buffalo hump,” appear with progression of the disease. Decreased muscle mass and proximal limb weakness occur from atrophy of muscle fibers induced by the high level of cortisol, which inhibits protein synthesis and uptake of glucose by the cells. Patients with Cushing syndrome often have elevated blood glucose levels with glucosuria. Other clinical signs and symptoms include striae of the skin, osteoporosis, hirsutism, menstrual abnormalities in women, and mental status changes involving mood swings with depression.

Cushing syndrome is separated into 3 main disease entities, with increased synthesis and loss of circadian rhythm resulting in excess cortisol production by the adrenal cortex as the common theme. Independent of the 3 naturally occurring forms of Cushing syndrome, the administration of glucocorticoids as a medication is a common cause of Cushing syndrome. This should be evident from the medication history. Endogenous forms of Cushing syndrome are described as follows:

- **Cushing disease** is the most common form of Cushing syndrome and is 4- to 6-fold more prevalent in women. It is caused most often by small ACTH-secreting tumors in the pituitary (<1 cm in size) known as microadenomas. These adenomas can be detected with various radiographic techniques after appropriate hormone tests suggest a pituitary etiology. On rare occasions, the tumors are large and present as macroadenomas.
- **Adrenal Cushing syndrome**—This form of Cushing syndrome is most commonly associated with a benign or malignant tumor in the adrenal cortex. Adrenal adenomas synthesize cortisol efficiently, but adrenal carcinomas often synthesize cortisol inefficiently and overproduce sex steroids, resulting in virilization.
- **Cushing syndrome from ectopic ACTH production**—Small cell lung carcinoma and bronchial carcinoid patients account for most of the Cushing syndrome cases in this category. This form of Cushing syndrome is more common in men because of the higher incidence of lung cancer in men. In the absence of signs and symptoms specifically associated with the lung carcinoma or carcinoid, these patients are clinically indistinguishable from those with pituitary Cushing disease. Because the syndrome often appears in patients with significant clinical manifestations of cancer, the symptoms from ectopic ACTH production often go...
unrecognized. Another very rare cause of Cushing syndrome with an ectopic focus and high serum ACTH level is a tumor, most frequently a bronchial carcinoid tumor, which secretes CRH instead of ACTH.

**Diagnosis**

The diagnosis of Cushing syndrome, or Cushing disease, discussed below collectively as Cushing syndrome, requires evidence of increased cortisol production and loss of suppression of cortisol synthesis or loss of cortisol diurnal variation. Screening for Cushing syndrome is difficult because 1) its prevalence is low; 2) several common conditions can produce biochemical and clinical signs of hypercortisolism in the absence of Cushing syndrome; and 3) the screening tests have a high rate of false-positive results for Cushing syndrome. For this reason it is recommended that a careful history be taken to exclude exogenous causes of hypercortisolism and that only patients with high clinical suspicion, such as those with unusual symptoms, for example, osteoporosis and less than 40 years old, children with a decrease in height and increase in weight percentiles, severe symptoms, or adrenal tumors visualized by imaging, be screened for Cushing syndrome.

The strategy for the diagnosis of Cushing syndrome, and the subsequent identification of 1 of the 3 forms of Cushing syndrome, involves tests to confirm endogenous hypercortisolism and then to determine whether the disease is ACTH-dependent. ACTH concentrations are low in patients with adrenal tumors, but normal or elevated with pituitary or ectopic ACTH-producing tumors. Table 22–2 summarizes the laboratory evaluation for Cushing syndrome.

The following steps to diagnose and differentiate Cushing syndrome can be made using first-line and then second-line diagnostic tests, respectively.

**Diagnostic Evaluation**

It is recommended that at least one of the following testing strategies be performed to diagnose patients with Cushing syndrome:

1. The 24-hour UFC or late-night salivary cortisol is a sensitive screening test for patients with clinical signs and symptoms of Cushing syndrome. Because of the variability of the cortisol concentrations, the UFC or salivary cortisol should be elevated on at least 2 separate occasions in order to proceed with the diagnostic evaluation for Cushing syndrome. If the UFC or salivary cortisol is normal in a high-risk patient, an endocrinologist should be consulted for further studies. A low-risk patient with normal results should be rescreened in 6 months if signs or symptoms persist or worsen.

2. In unhealthy, but not critically ill, patients, and/or those with abnormal renal function, or disrupted sleep patterns, physicians should use one of the LDDSTs to screen for Cushing syndrome. If cortisol production is suppressed by a low dose of dexamethasone in an overnight or 48-hour test, Cushing syndrome is ruled out. If the clinical suspicion

ACTH, adrenocorticotropic hormone (corticotropin).
for Cushing syndrome is still high in the presence of a nonsuggestive result for Cushing syndrome, further evaluation by an endocrinologist may be useful. A lack of cortisol suppression after a low dose of dexamethasone is suggestive of Cushing syndrome. Patients taking oral estrogens should not be screened with the LDDST, as estrogens stimulate the liver to synthesize cortisol-binding globulin (CBG) and elevate serum cortisol concentrations, causing false-positive screening results. Further, critically ill patients synthesize less CBG and albumin, leading to lower serum cortisol concentrations, and possibly false-negative screening results.

3. Other clinical conditions that cause hypercortisolism should be ruled out. These include alcoholism, severe obesity, pregnancy, depression, diabetes mellitus, and glucocorticoid resistance.

**Tests to Identify Etiology**

Once Cushing syndrome is confirmed, a series of tests can then be performed to locate the cause of the hypercortisolism.

1. Plasma ACTH testing should be performed to determine the etiology of the hypercortisolism. If ACTH is suppressed, an adrenal source is suspected. If ACTH is high or inappropriately normal, the patient may have a pituitary adenoma.

2. If an ACTH-secreting pituitary adenoma is suspected, MRI of the pituitary gland to identify a mass or petrosal sinus blood sampling to collect samples coming directly out of the pituitary after CRH stimulation is used as a confirmation test. A ratio of petrosal ACTH to serum ACTH above suggested cutoff values before and after CRH administration is consistent with a pituitary cause.

3. If the ACTH is suppressed, a CT of the adrenal glands is likely to be informative to identify an adrenal tumor and indicate an adrenal cause.

4. If an ectopic ACTH-secreting tumor is suspected, this can be challenging to locate, but imaging studies are often valuable. Chest, pancreas, colon, and gall bladder carcinomas have been shown to be sources of cortisol secretion.

“Pseudo-Cushing syndrome,” which can be produced by alcohol abuse and other disorders, mimics both the clinical and biochemical features of the true syndrome.

**Hypofunction Involving Glucocorticoids With or Without Mineralocorticoids: Adrenal Insufficiency**

**Description**

Adrenal insufficiency can be either primary, from destruction of the adrenal cortex by a local disease process or a systemic disorder, or secondary from pituitary or hypothalamic disease that reduces stimulation of the adrenal gland. The most common causes of primary adrenal insufficiency, in which all classes of adrenal cortical steroids are deficient, are autoimmune adrenalitis and tuberculosis in endemic regions. In this particular disorder, the adrenal medulla and its catecholamine synthesis are spared. In other primary adrenal insufficiency disorders in which the adrenal gland is damaged, the adrenal medulla may be damaged along with the adrenal cortex. In secondary adrenal insufficiency, in which there is deficient stimulation of the adrenal gland because of pituitary or hypothalamic abnormalities, the adrenal medulla is not affected and aldosterone deficiency is not usually present. Aldosterone secretion is more dependent on angiotensin II stimulation of the adrenal cortex than on stimulation of the adrenal cortex by ACTH (as discussed below).

- **Primary adrenal insufficiency**—There are many causes of primary adrenal insufficiency. Dysfunction in 1 or more sites in the HPA axis is the major cause of the primary adrenal insufficiency. Chronic primary adrenal insufficiency, also known as Addison disease, occurs mostly in adults. The most common causes are autoimmune disease (Western world) and tuberculous adrenalitis (worldwide). Other causes of primary adrenal insufficiency include fungal or viral infections (ie, histoplasmosis or HIV), and anatomic destruction of the adrenal glands through surgery, hemorrhage, or metastatic carcinomas. Primary adrenal
insufficiency is characterized by hyperpigmentation of the skin and mucous membranes. The lack of negative feedback from adrenal cortisol leads to increased ACTH production by the pituitary. A degradation product of ACTH and its prohormone pro-opiomelanocortin is melanocyte-stimulating hormone (MSH). MSH stimulates melanin production and induces melanocyte hyperpigmentation. Hyperkalemia and hypotension may be present if there is deficient aldosterone (see the sections “Primary Hypoaldosteronism” and “Secondary Hypoaldosteronism”). Primary adrenal insufficiency usually has a gradual onset but may occur abruptly with a stressor such as critical illness or surgery. The rapid onset form of adrenal insufficiency is often the result of adrenal hemorrhage or thrombosis that impairs blood supply to the gland.

Acute primary adrenocortical failure (also called Addisonian crisis) can be triggered by a severe infection, sepsis, or abrupt withdrawal of steroids. It is a life-threatening emergency, characterized by abnormal electrolytes (critically high potassium and low sodium), hypotension, and hypoglycemia. Sudden death can occur if it is not treated promptly.

- **Secondary adrenal insufficiency**—A deficiency of ACTH secretion from any cause can lead to adrenal insufficiency. Long-term glucocorticoid therapy can result in prolonged suppression of CRH from the hypothalamus and ACTH from the pituitary and transient adrenal insufficiency. Hypopituitarism as a result of postpartum hemorrhage (Sheehan syndrome), radiation, surgery, or injury may result in decreased ACTH production leading to reduced glucocorticoid synthesis.

**Diagnosis**

The management of adrenal insufficiency first requires determination of the disease source (ie, primary or secondary), followed by an identification of the specific cause for the adrenal insufficiency. The tests that are useful in the diagnosis of primary and secondary adrenal insufficiency are shown in Table 22–3. Adrenal insufficiency may involve a deficiency of glucocorticoids or both glucocorticoids and mineralocorticoids. Depending on the extent of adrenal cortex damage, patients may have decreased serum cortisol and/or decreased plasma aldosterone levels.

ACTH, adrenocorticotropic hormone (corticotropin); CRH, corticotropin-releasing hormone.
CHAPTER 22  The Endocrine System

The ACTH stimulation test is the most specific test to confirm a diagnosis of adrenal insufficiency. Patients with primary adrenal insufficiency do not usually show cortisol secretion following ACTH stimulation because the defect is within the adrenal gland. Patients with mild or recent onset of secondary adrenal insufficiency (and a still viable adrenal cortex) respond to the ACTH because the defect is not within the adrenal gland. A chronic lack of stimulation of the adrenal cortex by ACTH in secondary adrenal insufficiency can result in cortical atrophy and limited cortisol production following ACTH stimulation. The CRH stimulation test can distinguish between secondary adrenal insufficiency caused by ACTH deficiency and that caused by CRH deficiency. Plasma ACTH and serum cortisol are measured after administration of CRH; increases are observed in hypothalamic disorders, but not in pituitary disorders. A serologic test for antiadrenal antibodies is useful to determine if autoimmune adrenalitis is the cause of primary adrenal insufficiency.

Hyperfunction and Hypofunction Involving Mineralocorticoids: Hyperaldosteronism and Hypoaldosteronism

Description and Diagnosis

Aldosterone is a mineralocorticoid produced in the adrenal glands. It is largely responsible for regulating sodium retention and water resorption, and thereby control of blood volume. It also promotes the excretion of potassium into the urine. Aldosterone concentration in the blood is regulated by the renin–angiotensin aldosterone (RAA) system. In response to decreased blood volume, the juxtaglomerular apparatus of the kidney secretes renin, which converts angiotensinogen to angiotensin I. Angiotensin I is converted to angiotensin II by angiotensin-converting enzyme in the lungs. Angiotensin II is a potent vasoconstrictor and also stimulates the adrenal glands to secrete aldosterone, which then acts to increase blood volume by promoting sodium retention in exchange for potassium that is lost into the urine.

Aldosterone concentrations in disease may be high (hyperaldosteronism) or low (hypoaldosteronism). An abnormal (high or low) PAC may be the result of a defect originating inside (primary disorder) or outside (secondary disorder) of the adrenal gland (Table 22–4).

Primary Hyperaldosteronism
In this disorder, there is excess secretion of aldosterone as a result of an abnormality within the adrenal gland. Most often, hyperaldosteronism is caused by bilateral hyperplasia of the adrenal glands or by an aldosterone-secreting adrenal adenoma, resulting in a disorder known as Conn syndrome. Less often, primary hyperaldosteronism is a result of primary (unilateral) adrenal hyperplasia or a cancerous tumor. In primary hyperaldosteronism, the PRA is low because aldosterone stimulates high sodium concentrations and increased blood volume triggers downregulation of renin secretion. The ratio of the PAC/PRA is widely used as a screening test for primary aldosteronism in hypertensive patients. A ratio of greater than 30 when PAC is measured in conventional units (ng/dL) and 750 when PAC is in SI units (pmol/L) is the most commonly used cutoff to identify patients with this disorder. Because of the effect of numerous drugs, diet, and comorbidities on PAC and PRA concentrations, it is recommended that along with an elevated ratio, patients also have PAC concentrations above 15 ng/dL. Some laboratories use DRC as an indirect measure of renin activity. A few studies have published recommended diagnostic cutoffs for the PAC/DRC ratios for primary hyperaldosteronism, but they have not yet been universally accepted.

Secondary Hyperaldosteronism
In this disorder, there is excess secretion of aldosterone as a result of an abnormality outside the adrenal gland. It is much more common than primary hyperaldosteronism. Decreased renal perfusion is the most common cause of secondary hyperaldosteronism. The decreased blood flow into the kidney results in an elevation of the PRA. The elevation in plasma renin level (as shown in Figure 22–6) produces the increase in aldosterone. Congestive heart failure, nephrotic syndrome, cirrhosis of the liver, and other hypoproteinemic conditions in which there is chronic depletion of plasma volume can produce an elevation in plasma aldosterone.

The clinical and laboratory features common to both primary and secondary hyperaldosteronism usually include hypertension associated with hypervolemia and low or low-normal concentrations of serum potassium. The serum sodium also may be slightly elevated. Additional clinical features include nocturnal polyuria, polydipsia, and weakness from the low potassium concentrations.

Primary Hypoaldosteronism
This disorder is much less common than primary hyperaldosteronism. Primary hypoaldosteronism is most often a result of destruction of the adrenal gland from various causes (as noted in the section “Hypofunction Involving Glucocorticoids With or Without Mineralocorticoids: Adrenal Insufficiency”), including autoimmune adrenalitis, adrenal infection by tuberculosis, metastatic tumors to the adrenal, adrenalectomy, CAH associated with low aldosterone production (see the section “Alterations in the Synthesis of Glucocorticoids, Mineralocorticoids, and Sex Steroids: Congenital Adrenal Hyperplasia”), and hemorrhage into the adrenal gland. There is an additional disorder associated with primary hypoaldosteronism, known as pseudohypoaldosteronism, in which the tissues are resistant to the action of aldosterone. Low blood volume and/or sodium due to lack of aldosterone action upregulates renin synthesis, which subsequently upregulates aldosterone. Therefore, these patients have significantly elevated PAC and PRA.

Secondary Hypoaldosteronism
In this disorder, aldosterone hyposecretion results from factors originating outside the adrenal gland. One cause is a deficiency of ACTH production in the pituitary, often accompanied by deficiencies of other pituitary hormones. As noted earlier, the adrenal cortex can become atrophied as a result of a chronic lack of stimulation by ACTH, decreasing aldosterone as well as cortisol production. Another cause is long-term glucocorticoid administration. Long-term glucocorticoid-induced ACTH suppression leads to adrenal atrophy and reduced aldosterone synthesis. Secondary hypoaldosteronism can also occur as a result of deficient renin production due to renal damage or drugs and from inhibition of angiotensin-converting enzyme by drugs. Clinical and laboratory features common to primary and secondary hypoaldosteronism include hypotension, which may be orthostatic, and high serum potassium levels. Slightly low serum sodium values also may be present. The clinical signs and symptoms vary significantly and depend on the specific defect leading to the hypoaldosteronism.
Alterations in the Synthesis of Glucocorticoids, Mineralocorticoids, and Sex Steroids: Congenital Adrenal Hyperplasia

Description and Diagnosis

CAH is caused by any 1 of a group of enzyme deficiencies in the biosynthetic pathways for cortisol and aldosterone. Because cortisol production is decreased, and cortisol provides the inhibitory feedback to the pituitary for ACTH secretion, there is an increase in ACTH and excess stimulation of the adrenal glands (see Figures 22–5 and 22–6 for the regulation of cortisol and aldosterone production). This results in greater flux through pathways around an existing enzymatic defect, producing elevations in adrenal hormones whose synthesis is not affected by the enzyme deficiency. Most of the known enzyme deficiencies in the synthetic pathways for aldosterone and cortisol result in an elevation in sex steroid synthesis, which has a virilizing effect on the patient. The most common of the enzymatic defects is a deficiency of 21-hydroxylase. This deficiency accounts for 90% to 95% of the cases of CAH. The clinical manifestations for 4 of the enzyme deficiencies producing CAH are noted below. Figure 22–4 shows the intermediate compounds in the synthesis of aldosterone, cortisol, and androgens in the adrenal gland and the enzymes in the pathway, some of which may be deficient.

ACTH, adrenocorticotropic hormone (corticotropin); DHEA, dehydroepiandrosterone.
• **11-Beta-hydroxylase deficiency**—This is the second most common enzyme deficiency responsible for CAH. In infancy, the clinical and laboratory features of patients with this abnormality are largely similar to those found in patients with 21-hydroxylase deficiency. However, deficiency of this enzyme causes accumulation of 11-deoxycorticosterone, a potent mineralocorticoid. Thus, these patients develop mineralocorticoid-induced hypertension and hypokalemia.

• **17-Alpha-hydroxylase deficiency**—This deficiency is rare and accounts for approximately 1% of all CAH cases. In this deficiency, there is no inhibition of aldosterone synthesis, but there is a block in the synthesis of both cortisol and sex steroids. The elevation of aldosterone results in hyperaldosteronism that produces hypertension and hypokalemia. In females, the androgen deficiency results in a lack of development of secondary sex characteristics because the androgens are biochemical precursors of estrogens. In males, pseudohermaphroditism appears.

• **3-Beta-hydroxysteroid dehydrogenase deficiency**—This is another rare CAH disorder. This enzymatic deficiency results in a metabolic block in the production of aldosterone and cortisol, with no inhibition of the synthesis of DHEA and other androgens. In its severe form, this enzyme deficiency manifests as early masculinization in males and amenorrhea and pseudohermaphroditism in females, as well as life-threatening hyperkalemia, hyponatremia, and hypotension.

**ADRENAL MEDULLA**

**Physiology and Biochemistry**

The main sites of production of the catecholamines are the brain, the chromaffin cells of the adrenal medulla, and the sympathetic neurons. The catecholamines include dopamine, epinephrine, and norepinephrine as the most potent of the endogenously produced compounds. Of these, in the adrenal medulla, epinephrine production is quantitatively the greatest. The catecholamines have a wide variety of biological effects. They have a marked impact on the vascular system, and are important in blood pressure regulation. Epinephrine influences many metabolic pathways, especially carbohydrate metabolism. In some tissues, epinephrine and norepinephrine produce opposite effects. Alpha-adrenergic receptors on cells interact effectively with norepinephrine and moderately with epinephrine, while beta-adrenergic receptors respond primarily to epinephrine and norepinephrine.

Catecholamine synthesis and metabolism in the adrenal medulla is illustrated in Figure 22–7. The pathway begins when the amino acid tyrosine is metabolized to a catecholamine, dihydroxyphenylalanine (DOPA). DOPA is then converted to dopamine, which is transformed to norepinephrine, which is subsequently converted to epinephrine. Because of their great potency, the catecholamines must be rapidly inactivated through reuptake into storage granules, conversion to metabolites, or excretion. Unlike the steroid hormones, catecholamines are not bound to proteins as they circulate. In plasma, they have a very short half-life of approximately 2 minutes. Urine catecholamines, on the other hand, represent a pool of catecholamines delivered into urine in the preceding hours. There are a number of degradative products of epinephrine and norepinephrine. The compounds noted in Figure 22–7—metanephrine, normetanephrine, and vanillylmandelic acid—are the ones that are measured in clinical assays to assess catecholamine production and degradation.

**Laboratory Tests**

**Epinephrine and Norepinephrine**

Total or fractionated (epinephrine or norepinephrine) catecholamines can be measured in plasma or 24-hour urine samples. The plasma concentration reflects the rate of synthesis and release of catecholamines by the adrenal medulla and their half-life in the circulation. Catecholamines are secreted into the urine as free hormones. Urinary catecholamines are extremely unstable and should be acidified during or right after collection.
CHAPTER 22  The Endocrine System

Metanephrines (Metanephrine and Normetanephrine)
The preferred screening test for adrenal medullary neuroendocrine tumors is detection of free metanephrines and normetanephrines in plasma. Both metanephrine and normetanephrine undergo conjugation with sulfate or glucuronide. The metanephrines can also be measured in a 24-hour urine specimen. Urine measurements are helpful in cases where plasma metanephrines are marginally elevated. Metanephrines are also unstable in urine and should be acidified during or right after collection.

Vanillylmandelic Acid
This compound is the major metabolite of both metanephrine and normetanephrine. It is measured in the urine and, although it is indicative of catecholamine synthesis and metabolism, it is inferior to urinary metanephrine quantitation for this purpose.

Pheochromocytoma
Description
A pheochromocytoma, which may be benign or malignant, is a chromaffin cell tumor of the adrenal medulla or autonomic nervous system that secretes catecholamines. On this basis, it is a cause of hypertension. However, it is a rare cause of hypertension with approximately 5 pheochromocytomas per 100,000 hypertensive cases. Other catecholamine-secreting chromaffin cell tumors are paragangliomas and neuroblastomas. It is essential that a pheochromocytoma be rapidly and accurately identified in patients with hypertension because surgical resection of the tumor, with elimination of the hypertension and its complications, is successful in at least 90% of cases, and the disease may be otherwise fatal. The diagnosis is made most often in patients between the ages of 30 and 60 years. The clinical features of a patient with pheochromocytoma

FIGURE 22–7  Catecholamine synthesis and metabolism in the adrenal medulla.
include, most importantly, the presence of sustained or paroxysmal hypertension. The attacks of hypertension occur abruptly and subside slowly, with a total duration of less than 1 hour in approximately 80% of patients. They may be precipitated by palpation of the tumor, postural changes, exertion, anxiety, trauma, pain, intake of foods or beverages containing tyramine (such as certain cheeses, beer, and wine), and the ingestion of certain medications. Headaches are common in patients with pheochromocytoma, and they are usually severe. Generalized sweating and palpitations with tachycardia occur frequently. Other common signs and symptoms are anxiety, chest pain, nausea, fatigue, and weight loss. Of all pheochromocytomas, approximately 25% to 30% are familial and coexist with a form of multiple endocrine neoplasia (MEN), von Hippel Lindau, neurofibromatosis, or succinate dehydrogenase (SDH) mutation (see later section); 10% of inherited pheochromocytomas are malignant; 10% are extra-adrenal in location and are called paragangliomas (and therefore 90% are in the adrenal); and 10% are bilateral and most of these are patients with MEN 2A.

**Diagnosis**

As noted before, the most biologically significant catecholamines synthesized by a pheochromocytoma are epinephrine and norepinephrine. These compounds are metabolized into metanephrine and normetanephrine, respectively (Figure 22–7), and both of these compounds can be metabolized to vanillylmandelic acid. Measurement of fractionated, free plasma metanephrines is the preferred screening test to rule out pheochromocytoma. This test measures plasma levels of free metanephrine and free normetanephrine as separate compounds. All patients with clinical symptoms and elevated plasma free metanephrines should undergo localization studies with an adrenal CT scan or MIBG (an imaging study involving the use of the radioisotope MIBG). Follow-up testing for patients with suspected pheochromocytoma and a borderline positive plasma metanephrine screening test include measurement of metanephrines in a 24-hour urine sample and then fractionated catecholamines in plasma or urine. The diagnosis of pheochromocytoma is based on the detection of increased concentrations of urinary or plasma metanephrines, and possibly plasma or urinary catecholamines, in the appropriate clinical setting of sustained or paroxysmal hypertension. Adrenal CT or other radiographic techniques can be used to localize a pheochromocytoma. Laboratory tests used for diagnosis of pheochromocytoma are described in Table 22–6.

**TABLE 22–6 Laboratory Evaluation for Pheochromocytoma**

</table>

It is essential that a pheochromocytoma be rapidly and accurately identified in patients with hypertension because surgical resection of the tumor, with elimination of the hypertension and its complications, is successful in at least 90% of cases, and the disease may be otherwise fatal.
PARATHYROID GLANDS

This section is focused on parathyroid hormone (PTH) and disorders associated with high or low concentrations of this hormone. Most parathyroid disorders alter calcium metabolism, and thereby have an effect on bone. However, there are also a number of disorders associated with hypercalcemia or hypocalcemia, or alterations in bone density, in which a change in the PTH level is not a major factor. Therefore, in addition to hyperparathyroidism and hypoparathyroidism, this chapter also briefly describes a few selected disorders associated with hypercalcemia, hypocalcemia, or altered bone density in which PTH does not play a major role.

Physiology and Biochemistry

PTH is a polypeptide secreted from the parathyroid glands. The primary function of PTH is the regulation of the concentration of ionized calcium in extracellular fluids. An increase in secretion of PTH produces a rise in serum ionized calcium and a decrease in the serum phosphorus concentration. A normal or an elevated blood calcium provides negative feedback to the parathyroid gland to reduce the secretion of PTH (see Figure 22–8).

The resorption of bone induced by PTH is mediated by increased activity of osteoclasts. PTH can also promote an increase in the renal tubular reabsorption of calcium.

Vitamin D is an intermediary in the action of PTH to elevate the serum calcium level. It is a fat-soluble hormone required for calcium absorption in the gut, bone metabolism, and development of cells in the immune system. Vitamin D also influences phosphorus metabolism. Vitamin D₂ is known as ergocalciferol, and vitamin D₃ is known as cholecalciferol.

Food can be fortified with either vitamin D₂ or D₃, both of which can be used as vitamin D supplements. Cholecalciferol is ingested in the diet, and it is also synthesized in the skin upon ultraviolet irradiation of 7-dehydrocholesterol. The cholecalciferol is transported to the liver where it is hydroxylated to produce 25-hydroxycholecalciferol (25-(OH)D₃). The 25-(OH)D₃ has limited biological activity, but in the kidney it undergoes further hydroxylation to form dihydroxy metabolites, the most potent of which in calcium metabolism is 1,25-(OH)₂D₃. An increase in this vitamin D metabolite results in increased intestinal absorption of calcium, mobilization of calcium and phosphorous from the bone, and increased calcium reabsorption in the kidney, all acting to elevate plasma calcium concentrations. The production of this dihydroxy metabolite of vitamin D is regulated by the need for calcium in the circulation. Decreased blood calcium results in a stimulation of the parathyroid glands to secrete PTH that leads to the increased production of 1,25-(OH)₂D₃ in the renal proximal tubules. Thus, PTH is responsible for maintaining the necessary levels of calcium in the body by extracting sufficient calcium from the diet, resorbing it from bone, or preventing its excretion through the renal tubules. Figure 22–8 shows the regulation of PTH secretion. Ingested vitamin D₃ is hydroxylated into 25-(OH)D₃ and follows the same metabolism to 1,25-(OH)₂D₃.

Calcitonin has an opposing action to PTH, but in humans it appears to play a minor role in calcium homeostasis. As a drug, its pharmacologic action is more definitive. It inhibits osteoclastic bone resorption. It also decreases renal tubular reabsorption of calcium, and by these mechanisms opposes the action of PTH. Calcitonin synthesis occurs in the parafollicular C cells of the thyroid gland.

Approximately 98% of calcium is present in the body within the bones in the form of hydroxyapatite, a crystal lattice composed of calcium, phosphorus, and hydroxide. Of the calcium not within the bones, about half is present in extracellular fluid and the remainder is present in a variety of tissues, particularly skeletal muscle. Only about 1% of the calcium in the bones is exchangeable with the extracellular fluid, and it is this pool that is most significantly affected by changes in PTH concentration. Calcium exists in the plasma in 3 distinct forms: free or ionized calcium, protein-bound, and complexed with anions. Ionized calcium is the physiologically active form of calcium and accounts for approximately 45% to 50% of the total calcium in the plasma. Another 40% to 45% of calcium in the plasma is bound to plasma proteins. The protein that binds most of this calcium is albumin, but calcium also binds to some globulins. The remaining 5% to 15% of the total calcium forms a complex with a variety of anions. The most commonly found complexes are calcium phosphate and calcium citrate. The distribution of the 3 forms of calcium changes with alterations in pH in the extracellular fluid and with changes in plasma protein concentration.
In general, the serum ionized calcium increases in acidosis and decreases in alkalosis because calcium more easily binds proteins under alkalotic conditions. An increase in the concentration of plasma proteins that bind calcium results in a corresponding increase in total calcium, and a decrease in the plasma proteins may result in a decrease in total calcium.

The metabolism of phosphorus is linked to the metabolism of calcium. About 85% of the phosphorus in an adult is present in the bone as part of hydroxyapatite. Most of the remaining phosphorus in the body is within phospholipids, proteins, carbohydrates, nucleotides, and other important biochemical compounds. Phosphorus is present in virtually all foods, and dietary deficiencies do not occur. The phosphorus in the extracellular fluid exists primarily as $\text{HPO}_4^{2-}$ and $\text{H}_2\text{PO}_4^-$, which are collectively known as inorganic phosphorus. The relative amounts of these 2 phosphate anions are pH-dependent. Food ingestion can alter the serum inorganic phosphorus concentration significantly, with an increase in serum phosphorus concentration following the ingestion of phosphate-rich food. Because of the rapidly growing skeletal system, phosphorous demands and serum concentrations are significantly higher in children.

**Laboratory Tests**

**Calcium**

Whole blood, serum, or plasma specimens can be used for measurement of total calcium levels. For accurate measurement of the ionized or free form of calcium, the specimen must be transported on ice and must not be exposed to air.

**Inorganic Phosphorus**

About 15% of the inorganic phosphorus, predominantly $\text{HPO}_4^{2-}$ and $\text{H}_2\text{PO}_4^-$, in the plasma is protein-bound, and the remainder is free or complexed to another ion. Organic phosphorus...
(not measured in the assay for inorganic phosphorus) refers to the phosphorus within phospholipids, proteins, carbohydrates, nucleic acids, and other organic substances.

**PTH**

The most important test in the differential diagnosis of hypercalcemia is the assay for serum PTH. The biological activity of PTH resides in the first 34-amino terminal amino acids.

The intact hormone (iPTH) with 84 amino acids accounts for much of the circulating PTH, but there are many circulating PTH fragments. The assay for iPTH has largely superseded earlier tests that recognize numerous inactive circulating PTH fragments. One fragment of interest is the fragment of PTH representing amino acids 7-84 that is present in high concentrations during renal disease and capable of antagonizing the PTH receptor. Many newer iPTH assays still recognize the 7-84 fragment, along with the intact molecule, and therefore may not be less clinically informative. An assay for whole PTH is available that only recognizes the 1-84 amino acid PTH.

**Intraoperative PTH Assay**

Primary hyperparathyroidism requiring parathyroidectomy is a challenge because of variability in the location and number of parathyroid glands. Of parathyroid adenomas, 15% to 20% are ectopic, and not adjacent to the thyroid gland, and approximately 5% of patients have 5 parathyroid glands rather than 4. The success of parathyroid surgery has been improved by intraoperative PTH measurement. The relatively short half-life of PTH has allowed for surgeons to measure plasma PTH concentrations before and after excision of parathyroid tumors in surgery. A decrease in PTH of >50% after resection suggests complete resection of the tumor. Use of this intraoperative test has resulted in a higher incidence of complete removal of hypersecreting parathyroid gland tissue, reduced the need for extensive exploration of the neck, and decreased the need for repeat surgery.

**Vitamin D**

The quantitation of selected vitamin D metabolites is useful in assessing vitamin D metabolism. Vitamin D metabolites of greatest relevance to calcium metabolism include 25-(OH)D$_3$ (also known as 25-hydroxyvitamin D) and 1,25-(OH)$_2$D$_3$ (also known as 1,25-dihydroxyvitamin D). Currently the most commonly ordered test, as a screening test for vitamin D deficiency, is the total 25-(OH) vitamin D, which is the sum of the 25-(OH) vitamin D$_2$ and 25-(OH) vitamin D$_3$ concentrations in serum. Recently, tandem mass spectrometry has increased in use and allowed for measurement of vitamin D$_2$ and vitamin D$_3$ in either form (ie, 25-(OH) or 1,25-(OH)) in a single test. 25-(OH) vitamin D is the most abundant metabolite of vitamin D, and it has a long half-life. It is the component measured in most immunoassays for vitamin D. In contrast, 1,25-(OH)$_2$ vitamin D has a much lower serum concentration, and a shorter half-life (4-6 hours).

**PTH-related Protein (PTHRP)**

This protein, nearly twice the size of PTH, is equipotent with PTH in inducing hypercalcemia. PTHrP is secreted by numerous tumor tissues. Its shared homology allows PTHrP to bind PTH receptors and stimulate renal proximal tubular reabsorption of calcium. The assay to measure PTHrP shows less than 1% cross-reactivity with PTH.

**Bone Markers**

Markers for bone turnover can be classified into 2 groups, markers of bone formation and markers for bone resorption. Bone markers should not be used as definitive tests for the diagnosis of osteoporosis. Their primary utility is to monitor response to treatment for bone disease. The markers with the most clinical utility are described below.

**Bone Formation Markers**

**Alkaline Phosphatase.** This enzyme is present in a wide variety of tissues, one of which is the bone. Most laboratory assays for alkaline phosphatase (ALP) measure total ALP. The bone-derived
fraction of ALP can be differentiated from its isoenzymes in serum by bone-specific ALP immunoassay or based on its instability. Bone ALP is denatured by heat and urea. Falsely elevated results are commonly seen in liver disease.

**Osteocalcin.** Serum osteocalcin is a moderately specific marker for bone formation. Serum concentrations are highest in adolescence and in the newborn, when bone growth is most active, and in renal failure due to clearance impairment. The serum osteocalcin concentration rises in women from the 4th to the 10th decade as the bone turnover increases. Menopause induces a marked increase in bone turnover, often with an increase in serum osteocalcin. Although not as sensitive as collagen markers, measurement of osteocalcin can help predict bone loss in postmenopausal women.

**Procollagen Type I Intact N-terminal Propeptide (PINP).** PINP, which is formed during collagen synthesis, is the most sensitive marker of bone formation. Measurement of PINP by radioimmunoassay in serum is recommended for monitoring of therapy to bone disease. It should be measured prior to initiation of therapy and then subsequently 3 to 6 months later. PINP exhibits less intraindividual biovariability than other collagen markers.

**Bone Resorption Markers**

**N- and C-terminal Telopeptide of Type 1 Collagen (NTx and CTx).** NTx and CTx are peptide fragments formed during bone resorption through proteolytic processing of the N- and C-terminal ends of type I collagen, respectively. These can be measured by immunoassay in both serum and urine to assess response to treatment of bone disease. Significant intraindividual variability exists in CTx concentrations because it is affected by diet, exercise, and time of day. NTx should be measured prior to initiation of therapy and then 3 to 6 months later to assess bone disease status.

**Pyridinium Cross-links.** Pyridinium cross-links, including deoxypyridinoline (DPD), are a group of products formed during bone resorption as a result of collagen breakdown. These can be measured by immunoassay and are useful in monitoring therapy. Urine pyridinium cross-link concentrations can determine efficacy of bone disease treatment after as little as 2 months of therapy.

**Primary Hyperparathyroidism**

**Description**

In primary hyperparathyroidism, there is excess secretion of PTH in the absence of an appropriate stimulus. The disease affects women about twice as frequently as it affects men, and the incidence increases with age. The majority of cases of primary hyperparathyroidism result from a single parathyroid adenoma, with hyperplasia of the parathyroids and parathyroid carcinoma being less common causes. The hypercalcemia in hyperparathyroidism occurs as a result of the direct action of PTH to increase resorption of bone calcium, PTH-induced renal tubular reabsorption of calcium, and synthesis of 1,25-(OH)2D3 that promotes the intestinal absorption of calcium. Primary hyperparathyroidism is often identified in asymptomatic individuals who have an unexpected serum hypercalcemia. Symptomatic patients with primary hyperparathyroidism may present with kidney stones, hypertension, polyuria, chronic constipation, depression, neuromuscular dysfunction, recurrent pancreatitis, peptic ulcer, or an unexplained osteopenia.

**Diagnosis**

Primary hyperparathyroidism may be suspected in patients with an isolated elevated total calcium. In order to rule out effects of binding proteins, ionized calcium should also be determined, especially in patients with abnormally low serum concentrations of total protein or albumin. As noted earlier, the total serum calcium is 45% to 50% ionized, 40% to 45% protein-bound (mostly to albumin), and 10% to 15% complexed with small inorganic and organic ions. On demonstration of hypercalcemia, serum PTH and fasting serum phosphorus (because the phosphorus concentration in the serum is altered by diet) should be measured. Assays for PTH can measure the intact molecule, carboxy-terminal, or midregion segments. The use of the intact PTH assay is preferred, especially in patients with renal disease because PTH carboxy-terminal fragments can
accumulate with decreased renal function. The diagnosis of hyperparathyroidism is made when both persistent hypercalcemia and elevated serum PTH level are demonstrated. The serum inorganic phosphorus may be low or normal in patients with primary hyperparathyroidism. Patients with severe hyperparathyroidism can have bone pain, skeletal deformities, and even bone fractures (Table 22–7).

### Secondary Hyperparathyroidism

**Description**
Secondary hyperparathyroidism occurs when there is chronic hypocalcemia and an excessive compensatory secretion of PTH. Chronic hypocalcemia is often a result of vitamin D deficiency or renal disease with calcium losses into the urine. Inadequate dietary intake of calcium is a rare cause of hypocalcemia. Secondary hyperparathyroidism is often associated with bone disease due to PTH-mediated bone resorption and calcium release.

**Diagnosis**
In secondary hyperparathyroidism, there is an elevation in the PTH, but unlike primary hyperparathyroidism, the total and ionized calcium in the serum is low or normal. Tests to identify causes of primary hyperparathyroidism, such as a parathyroid adenoma, should have negative results. Tests should be performed to identify the cause of the chronic hypocalcemia leading to secondary hyperparathyroidism. Vitamin D deficiency and renal disease, as noted previously, are the most common causes of chronic hypocalcemia, and these may be diagnosed with the appropriate laboratory assays (Table 22–7).

### Hypoparathyroidism

**Description**
Hypoparathyroidism occurs most frequently with unintentional removal of the parathyroids in the surgical excision of the thyroid gland. In hypoparathyroidism, the total and ionized calcium levels in the serum are low, with a low or undetectable serum PTH concentration.

**Diagnosis**
In hypoparathyroidism, serum total and ionized calcium concentrations are low, with a low or undetectable serum PTH concentration. There is an elevation in the serum inorganic phosphorus associated with the decrease in serum calcium (Table 22–7).
**Pseudohypoparathyroidism**

**Description**
As the name implies, patients with pseudohypoparathyroidism have signs and symptoms that are characteristic of hypoparathyroidism. This disorder results from a resistance of the tissues to the action of PTH and not a PTH deficiency, hence the use of the term “pseudo.”

**Diagnosis**
Pseudohypoparathyroidism can be distinguished from true hypoparathyroidism by the high concentration of serum PTH, in the presence of a low serum calcium concentration, in patients with the signs and symptoms of hypoparathyroidism. In addition, patients with pseudohypoparathyroidism demonstrate a lack of metabolic response when infused with PTH.

**Vitamin D Deficiency**

**Description**
Vitamin D deficiency, a major cause of secondary hyperparathyroidism and hypocalcemia, is caused by insufficient sun exposure, decreased intestinal absorption, insufficient intake, renal or liver failure, and numerous genetic disorders with defects in vitamin D processing, receptors, or binding proteins. Vitamin D deficiency has recently been defined by the Institute of Medicine as total 25-(OH) vitamin D <20 ng/mL (50 nmol/L), but this cutoff is assay-dependent. Based on this cutoff, it is estimated that the prevalence of deficiency ranges from 20% to 100% of the elderly population, and varies among younger individuals by race, age, and sun exposure. Severe vitamin D deficiency in young children results in characteristic skeletal deformities known as rickets. Consistent with secondary hyperparathyroidism, patients with vitamin D deficiency develop bone disease often manifesting in osteomalacia, osteopenia, or osteoporosis. Vitamin D may also have a role in numerous other tissues. Evidence suggests that 1,25-(OH)\textsubscript{2} vitamin D may play a direct or indirect role in immune modulation, blood pressure regulation, insulin production, and cardiac muscle contractility. Vitamin D deficiency may be associated with colon, prostate, and breast cancer, autoimmune disease, diabetes, and cardiovascular disease.

**Diagnosis**
High-risk patients (pregnant women, elderly, or patients with darker skin pigmentation) should be screened for vitamin D deficiency by measurement of total 25-(OH) vitamin D. Concentrations less than 20 ng/mL or a different lab-defined cutoff indicate deficiency. It is not useful to measure 1,25-(OH)\textsubscript{2} vitamin D in suspected vitamin D deficiency because of its short half-life and tight regulation by numerous molecules. It is useful in the evaluation of patients with rare forms of inherited rickets. The cause, prognosis, and treatment strategies for vitamin D deficiency can be determined by also measuring PTH, magnesium, and phosphorous in plasma.

**Hypercalcemia of Malignancy**

**Description**
The most common cause of severe hypercalcemia in an inpatient hospital population is malignancy. Tumors most often associated with hypercalcemia of malignancy include breast carcinoma, multiple myeloma, and lung carcinoma. The serum calcium level may be elevated as a result of osteolysis in the bone from metastases or humoral-induced hypercalcemia. In humoral hypercalcemia of malignancy, tumor production of PTHrP stimulates the PTH receptors to induce hypercalcemia. The elevated calcium signals downregulation of PTH. The assay for PTHrP is potentially useful when malignancy is suspected as a cause of hypercalcemia.

**Diagnosis**
Hypercalcemia of malignancy must be differentiated from hyperparathyroidism. Patients with hypercalcemia of malignancy will have elevated total and ionized serum calcium, in the presence of suppressed or low PTH. The low PTH value is the differentiating feature of hypercalcemia of malignancy from primary and secondary hyperparathyroidism, which are associated with high
concentrations of serum PTH (Table 22–7). For patients in whom humorally induced hypercalcemia is suspected, the most specific confirmatory test is the assay for PTHrP.

**Hypocalciuric Hypercalcemia**

**Description**

Familial hypocalciuric hypercalcemia (FHH) is a rare familial disease most often associated with loss of function mutations in the calcium-sensing receptor gene product expressed in the parathyroid glands and kidneys. Normally, this receptor inhibits release of PTH from the parathyroid glands in the presence of high calcium. In the absence of a functioning receptor PTH release is uncontrolled, leading to elevated PTH and hypercalcemia. In the renal tubules, the calcium-sensing receptors inhibit calcium reabsorption in the presence of high calcium. Without this receptor, calcium is continuously reabsorbed and not excreted, accentuating the high serum concentrations and leading to low urine calcium concentrations (hypocalciuria). Patients who are heterozygous for this mutation typically have asymptomatic hypercalcemia, while those with 2 deficient calcium-sensing receptor genes may require parathyroidectomy in infancy.

**Diagnosis**

Although rare, FHH is important because there is significant overlap in clinical and biochemical parameters with primary hyperparathyroidism. Thus, it is recommended that the diagnostic evaluation include a combination of clinical, biochemical, and genetic tests. Clinically, patients with FHH are usually asymptomatic, while those with primary hyperparathyroidism have symptoms associated with elevated calcium as well as decreased bone density. FHH patients usually have a personal and family history of hypercalcemia while those with hyperparathyroidism may not. The laboratory workup for FHH shows elevated serum calcium and PTH, and usually a reduced urine calcium. There is variability in urine calcium concentrations. Therefore, the calcium:creatinine clearance ratio (CCCR) is the recommended test for identifying FHH. A CCCR <0.01 suggests FHH, while a ratio >0.02 likely represents primary hyperparathyroidism. For patients with a CCCR between 0.01 and 0.02, genetic identification of mutations in the calcium-sensing receptor gene confirms the diagnosis of FHH.

**Osteoporosis**

**Description**

Osteoporosis is the most common metabolic disease of the bone associated with decreased bone mass. The causes of osteoporosis are many and varied. Osteoporosis may be primary or secondary. It can occur in association with hyperparathyroidism as described before, as well as with Cushing syndrome, acromegaly, prolonged use of heparin, excess vitamin D intake, and immobilization, among other conditions and disorders.

Bone mineral density (BMD) studies are preferred for diagnosis of primary osteoporosis. BMD estimates obtained by imaging studies are compared with BMD in normal populations to generate a T-score. The WHO defines osteoporosis as a T-score ≤−2.5. T-scores between −1.0 and −2.4 confirm osteopenia. Laboratory testing is preferred for the evaluation of secondary disease. Bone turnover markers can be used to monitor treatment.

**Diagnosis**

Osteoporosis as a primary disorder is inferred by the absence of another disease known to induce osteoporosis. Primary osteoporosis is generally idiopathic, postmenopausal, or senile. Secondary osteoporosis is established by demonstrating an underlying process or treatment that leads to osteoporosis.

**Osteomalacia**

**Description**

Osteomalacia is deficient mineralization of bone that results from disturbances in calcium and phosphorus metabolism. It can result from a nutritional deficiency of vitamin D, defects in vitamin D
metabolism or action, defects in mineral metabolism, or disturbances of the bone cells in the bone matrix. When osteomalacia occurs before the cessation of growth, it is known as rickets. Skeletal deformities appear in rickets because of the compensatory overgrowth of epiphyseal cartilage.

**Diagnosis**
Radiographic studies can demonstrate the disorder. The specific cause for osteomalacia, if it is identified, is generally established with laboratory testing. There are many disorders associated with the decreased mineralization of the bone.

**Osteitis Deformans (Also Known as Paget Disease of Bone)**

**Description**
Osteitis deformans is associated with osteoclastic resorption of bone and extensive production of abnormal, poorly mineralized osteoid. This results in a bone that is structurally weak and prone to deformity and fracture. The disorder may involve 1 bone or may be more generalized.

**Diagnosis**
In osteitis deformans, ALP is significantly elevated, which reflects osteoblastic proliferation in the deformed bone. The serum calcium and inorganic phosphorus concentrations are usually normal, but may be increased in some patients.

**TESTES AND OVARIES**

**Male Physiology and Biochemistry**
The male testes serve 2 important functions (Figure 22–9). One is the production of sperm, and the other is the synthesis and secretion of androgens. Sertoli cells within the testes secrete inhibin, and this glycoprotein inhibits the pituitary secretion of follicle-stimulating hormone (FSH). FSH acts on the Sertoli cells to stimulate sperm production and the synthesis of inhibin. Leydig cells in the testes are responsible for the production of androgens. The Leydig cells in the testes receive stimulation by luteinizing hormone (LH) to promote the conversion of cholesterol, through many intermediates, to testosterone. Testosterone, one of the androgens, is important for maturation of sperm, production of male secondary sex characteristics, and providing negative feedback to the anterior pituitary and hypothalamus to reduce the stimulation of the male testes. The hormone secreted by the hypothalamus in the hypothalamic–pituitary–gonadal axis is gonadotropin-releasing hormone (GnRH). GnRH stimulates the release of both LH and FSH from the pituitary in pulsatile patterns. Higher values for LH and FSH are found in the early morning hours.

The androgens are a collection of 19 carbon steroids that produce masculinization and male secondary sex characteristics. The main androgen secreted by the Leydig cells of the testes is testosterone. Other androgens secreted by the testes include androstenedione and DHEA. These compounds can be metabolized to testosterone and dihydrotestosterone (DHT) in target tissues. Circulating testosterone is a precursor to DHT. As previously noted, a number of androgens are secreted by the adrenal glands, including DHEA, DHEA-sulfate (DHEA-S), androstenedione, and androstenediol. Women also produce testosterone, but only 5% to 10% as much as men. Testosterone, as well as androstenedione, can be converted to estrogens. In men approximately 6% to 8% of the testosterone is converted to DHT, but only about 0.3% to estradiol. Most of the testosterone and DHT in the plasma is bound to plasma proteins. Only approximately 3% is free. The 2 major proteins that bind testosterone and DHT are sex hormone-binding globulin (SHBG) and albumin. In men, approximately 45% to 65% of protein-bound testosterone is associated with SHBG and 35% to 50% is bound to albumin. Protein-bound testosterone in women is distributed approximately two thirds on SHBG and one third on albumin. The bioavailable testosterone includes the small fraction that is free and the portion that is weakly bound to albumin. Testosterone binds less efficiently to albumin, and therefore it is available for tissue uptake when associated with this protein. The main excretory metabolites of testosterone, androstenedione, and DHEA are collectively known as 17-ketosteroids that can be quantitated in the urine.
Laboratory Tests

Total Testosterone
Total testosterone measured by immunoassay is a commonly used first-line test in evaluating a suspected gonadal dysfunction in adult males. Total serum testosterone represents both protein-bound and non-protein-bound testosterone. Because it is subject to diurnal variation, testosterone should be measured in the morning.

Free and Weakly Bound Testosterone
This is the bioavailable pool of circulating testosterone. In cases where total testosterone is abnormal, free testosterone can be assessed as a part of a panel that determines bioavailable testosterone and SHBG. Testosterone and SHBG are measured by immunoassay, and concentrations of free and bioavailable testosterone are derived from a mathematical equation based on the constants for the binding of testosterone to albumin and/or SHBG. This assay is not recommended for women and children because the testosterone concentrations are much lower. Therefore, for women and children, testosterone and SHBG are measured by a more complex method, tandem mass spectrometry, and again free and bioavailable testosterone are determined by the same mathematical equation.

SHBG can be measured by immunoassay separately, but the utility is largely in evaluating bioavailable testosterone in men with suspected hypogonadism and women with hyperandrogenism.
Testosterone Precursors and Metabolites
Immunooassays are available for quantitation of DHT, androstenedione, DHEA, DHEA-S, and other related compounds. Large panel testing for adrenal and gonadal steroids measured by LC/MS/MS are also available, especially for the evaluation of suspected congenital adrenal hyperplasia.

DHEA and DHEA-S
Serum concentrations of DHEA and DHEA-S provide an assessment of adrenal androgen production, which may be altered in patients with various conditions, including adrenal hyperplasia, adrenal tumors, delayed puberty, and hirsutism. DHEA is almost entirely derived from the adrenal glands, and DHEA-S in the circulation originates mostly from the adrenal glands, although in men some of it is derived from the testes. DHEA-S is the preferred test for assessing a suspected adrenal androgen abnormality because addition of the sulfate group stabilizes DHEA, leading to higher concentrations and a longer half-life in circulation.

Urinary 17-Ketosteroids
As noted above, the 17-ketosteroids in the urine are a collection of metabolites of androgenic steroids secreted by the testes, the adrenal glands, and, in women, the ovaries. The urine 17-ketosteroid test detects androsterone, DHEA, and several other steroids. However, it does not detect cortisol, estrogens, pregnanediol, testosterone, and DHT because they do not have a ketone functional group. In men, approximately 33% of the urinary 17-ketosteroids represent metabolites of testosterone secreted by the testes, and most of the remaining 17-ketosteroids are derived from steroids generated in the adrenal glands. In women, the 17-ketosteroids are derived almost exclusively from androgens generated in the adrenal glands. The main purpose of measuring these steroid metabolites is to assess androgen production by the adrenal gland. However, in men, a decrease in 17-ketosteroids in the urine may result also from decreased production of testosterone by the testes. Although the urine 17-ketosteroids are sometimes ordered to evaluate male androgenic status, this test does not detect the major androgens—testosterone and DHT. Therefore, if low androgens are suspected, serum testosterone is the preferred test, rather than 17-ketosteroids. Many clinicians now prefer the assessment of serum DHEA-S over urinary 17-ketosteroids for investigation of adrenal androgen production because a 24-hour urine collection is not required and many drugs interfere with the measurement of 17-ketosteroids.

Disorders Affecting Male Reproduction

Description and Diagnosis

Hypogonadotropic Hypogonadism. Hypogonadotropic hypogonadism in males is associated with absent or decreased function of the testes. If this impairment is manifested early in life, sexual development is retarded. In hypogonadotropic hypogonadism, there is a defect in the hypothalamus or pituitary that reduces normal gonadal stimulation. There are many causes for this abnormality, including panhypopituitarism and GnRH deficiency. A deficiency of GnRH in the hypothalamus is responsible for the most common form of hypogonadotropic hypogonadism, Kallmann syndrome. Hypogonadism in men is diagnosed by at least 2 measurements showing of decreased total testosterone in serum with symptoms of androgen deficiency. If total testosterone results are borderline, hypogonadism can be confirmed by measuring free or bioavailable testosterone. Patients with hypogonadotropic hypogonadism have low testosterone and below normal or inappropriately normal serum concentrations of LH and FSH. Because there are many causes for the disorder, there is much heterogeneity in the severity of these hormonal deficiencies. A clinical picture of sexual infantilism and low levels of LH, FSH, and testosterone in the serum are characteristic features of hypogonadotropic hypogonadism. In order to differentiate pituitary or hypothalamic sources of this disease, prolactin or other measures of pituitary function or imaging studies may be helpful.

Hypergonadotropic Hypogonadism. This disorder results from a defect in the testes, which may be a result of injury to the testes. There is active stimulation of the testes, but they are unresponsive in this disorder. Apart from testicular injury, getting older is among the commonly encountered causes of hypergonadotropic hypogonadism. The disorder can also result from testicular damage from radiation or chemotherapy.

Patients with androgen insensitivity syndrome (AIS), as it is now called, have a severe defect in androgen action, with resistance to the masculinizing effect of the androgenic hormones. This results in a female habitus, with breast tissue and a vagina that ends in a blind pouch, and undescended male testes.
Patients with hypergonadotropic hypogonadism have elevated concentrations of LH and FSH in the presence of decreased levels of testosterone. When the source of the gonadal failure is unclear, karyotyping may identify chromosomal anomalies as the cause of the testicular abnormality.

Androgen Insensitivity Syndrome (Testicular Feminization Syndrome). Patients with androgen insensitivity syndrome (AIS), as it is now called, have a severe defect in androgen action, with resistance to the masculinizing effect of the androgenic hormones. This results in a female habitus, with breast tissue and a vagina that ends in a blind pouch, and undescended male testes.

The circulating concentration of testosterone in patients with AIS (Table 22–8) is normal or elevated for a male. An elevation in testosterone can result in estrogen formation in these individuals because testosterone is a precursor for estrogen. The serum concentration of LH is increased, presumably because of resistance to the negative feedback of testosterone within the pituitary and hypothalamus.

Erectile Dysfunction (Formerly Impotence). There are many causes for the persistent inability to develop or maintain a penile erection sufficient for intercourse and ejaculation. Although psychogenic impotence is the most common (up to 50%), there are many endocrinologic and nonendocrinologic disorders that are associated with impotence. These include vascular disease, diabetes mellitus, hypertension, neoplasms, and adverse drug effects.

An endocrinologic study of the patient may be pursued by measuring the serum testosterone in the early morning, along with LH and FSH, to assess the hypothalamic–pituitary–male gonadal axis for testosterone production. Chapter 19 has additional discussion of this topic.

Female Physiology and Biochemistry

The ovaries function to produce ova and secrete sex hormones, notably estrogens and progestins. Estrogens maintain the female secondary sex characteristics. They are also essential in the regulation of the menstrual cycle, and breast and uterine growth in the maintenance of pregnancy (see Chapter 20 for a discussion on pregnancy). The estrogens have a major impact on calcium metabolism, and the estrogen depletion associated with menopause results in a loss of bone mineral content. Most of the estrogens in the body are secreted by the ovarian follicles and the corpus luteum. During pregnancy, estrogen is also synthesized in the placenta. Only minute quantities are synthesized by the adrenals. The normal human ovary produces estrogens, progestins, and androgens, but the primary products are estradiol and progesterone. More than 20 different estrogens have been identified. Those with clinical importance are estradiol, also known as E₂; estrone, also denoted as E₁; and estriol, that is E₃. Estradiol is derived almost exclusively from the ovaries, and for that reason the serum estradiol level is considered a reflection of ovarian function. In the nonpregnant state, most of the estrogen (microgram quantities) is derived from the ovaries. In pregnant women, the major source of estrogen is the placenta, which secretes estriol as the major product in milligram amounts. Like most other steroid hormones, the vast majority of the circulating estrogen is bound to plasma proteins. More than 95% of circulating estradiol is bound with high affinity to SHBG and, less avidly, to albumin.

Progesterone is a female sex hormone in the progestin family that plays a central role in female reproductive endocrinology. It is involved in regulation of the menstrual cycle and is produced during pregnancy by the placenta. In the nonpregnant state, progesterone is produced
largely by the ovary. The adrenal cortex is only a minor source of progesterone production in both sexes, and progesterone is made in very small quantities in the testes in men. More than 90% of the progesterone is protein-bound in the circulation to corticosteroid-binding globulin. Progesterone can be metabolized to 3 groups of metabolites, one of which is the pregnanediols. Urinary pregnanediol concentration can be used as an index of endogenous production of progesterone because it correlates with alterations in progesterone synthesis and metabolism.

There is a tightly coordinated feedback system among the hypothalamus, anterior pituitary, and ovaries in adolescent and adult women to regulate menstruation. Each menstrual cycle consists of a follicular and a luteal phase. Day 1 is the first day of menstrual bleeding. The follicular phase is associated with follicle growth and is the first part of the cycle. Ovulation occurs around day 14 of the menstrual cycle, and the luteal phase follows in the last half of the cycle.

In general, follicular growth in the ovary is stimulated by FSH, and ovulation and progesterone secretion from the developing corpus luteum are driven by LH. During the menstrual cycle:

- FSH increases during the early part of the follicular phase and then declines until ovulation; there is a gradual decrease in FSH through the luteal phase. FSH guides selection of a dominant follicle.
- LH secretion increases around the middle of the follicular phase and just before ovulation; estrogen secretion in the follicular phase stimulates the pituitary to release LH in a surge, with the peak value for LH appearing 10 to 12 hours before ovulation.
- Estradiol concentrations increase as the selected dominant follicle begins to secrete this hormone during midfollicular phase. Its concentrations rapidly rise as the follicle matures. The estradiol concentration then falls abruptly just before ovulation. At ovulation the ovum is released from the follicle. The leftover tissue, called the corpus luteum, is essential for establishing early pregnancy. The corpus luteum secretes estradiol and progesterone to facilitate implantation. If the ovum is not fertilized, the corpus luteum breaks down and estradiol and progesterone synthesis decline after about 14 days. The decline in both hormones signals the beginning of the menstrual cycle.
- Progesterone is at very low concentrations during the follicular phase; with the midcycle surge of LH and ovulation, the corpus luteum secretes progesterone that increases and reaches its peak concentration approximately 8 days after the midcycle LH surge. As the corpus luteum degrades, progesterone concentrations decline to baseline levels at the end of the luteal phase.

*Figure 22–9* illustrates the complex relationships in the hypothalamic–pituitary–female gonadal axis.

**Laboratory Tests**

**Estrogens**

Serum estrogen levels are represented by the estradiol (E₂) concentration, because estriol (E₃) in a nonpregnant woman is derived almost exclusively from estradiol. In addition, blood estrone (E₁) levels typically parallel estradiol levels throughout the menstrual cycle, but at a lower concentration. Urinary estrogens can be quantitated as total estrogens or as fractionated estrogens with measurement of estradiol, estrone, and estriol. Since estradiol is derived primarily from the ovaries, the estradiol concentration in the urine can provide a more accurate reflection of ovarian function than total urinary estrogen.

**Progesterone**

The progesterone concentration in serum is a reflection of progesterone production. Assays for urinary progesterone metabolites are used much less frequently to assess progesterone synthesis than tests for serum progesterone.

**Endocrinologic Disorders Affecting Female Reproduction**

**Description and Diagnosis**

Healthy women display considerable variations in the length of the menstrual cycle, but most women have cycles between 25 and 30 days in length (see *Figure 22–10*). The absence of menstrual bleeding is known as amenorrhea. Primary amenorrhea refers to women who have never
Primary Amenorrhea. Primary amenorrhea is established if spontaneous regular menstruation has not begun by the age of 16 years, with or without the presence of secondary sex characteristics. The list of causes of primary amenorrhea is lengthy. They include lower genitourinary tract defects such as imperforate hymen; a host of ovarian disorders—approximately 40% of females with primary amenorrhea have Turner syndrome (45 X karyotype) or pure gonadal dysgenesis (either a 46 XX or XY karyotype); adrenal disorders such as CAH; thyroid disorders, notably hypothyroidism; pituitary–hypothalamic disorders such as hypopituitarism and Kallmann syndrome (which also affects men); and pregnancy.

Because of the long list of possible causes, the workup for primary amenorrhea should begin with a careful history and physical examination to look for anatomic defects, development of secondary sexual characteristics, and/or a personal or family history of short stature, infertility, and/or amenorrhea. The laboratory evaluation for amenorrhea begins with measurement of hCG to rule out pregnancy. If not pregnant, patients should undergo imaging studies looking for a uterus and gonads. Patients with a detectable uterus should be evaluated for hypothyroidism and hyperprolactinemia (discussed below). High TSH and low free T4 results suggest the amenorrhea is due to primary hypothyroidism. An elevated prolactin result should prompt a physician to perform an MRI in search of a pituitary adenoma. Patients with normal TSH and prolactin should be evaluated for gonadotropic function by measuring LH and FSH. Estrogen measurements may be helpful to determine the cause of disease. Because of the day-to-day variability in estrogen concentrations, the progestin challenge test may be helpful to establish estrogen reserves and/or etiology of primary amenorrhea. Theoretically, if progesterone is given to an estrogen-primed uterus, withdrawal bleeding (menstruation) will occur. Progesterone is given orally for up to 1 week. Bleeding should occur within 1 week of progesterone withdrawal if the woman’s ovaries have produced enough estrogen (>40 pg/mL serum) to prime her uterus.

If the patient has congenital anomalies, a karyotype evaluation to look for cytogenetic abnormalities may be helpful (Table 22–9).

Secondary Amenorrhea. Secondary amenorrhea is more common than primary amenorrhea and is the absence of regular menstruation for at least 6 months in a woman who has previously had menses. Oligomenorrhea is present if a woman has less than 9 menstrual cycles per year. The causes of secondary amenorrhea include many of those for primary amenorrhea. However, there are a number of conditions associated with secondary amenorrhea that are independent of primary amenorrhea. Most notably, pregnancy is a common cause of amenorrhea and must be considered first in a patient who has stopped menses. An elevated prolactin concentration, which may be induced by a prolactin-secreting tumor, can produce oligomenorrhea or amenorrhea,
presumably by inhibition of the release of LH and FSH by the prolactin. Patients with secondary amenorrhea can be divided into those with and without signs of hirsutism and androgen excess. Hirsutism is the excessive growth of terminal hair in women and in children, in a distribution similar to that which occurs in postpubertal men. Causes of hirsutism may be androgen-dependent, with abnormalities often originating in the ovary or the adrenal gland, or androgen-independent, sometimes from antiepileptic medications. Adult women with hirsutism and androgen excess may carry a diagnosis of adult-onset CAH, ACTH-dependent Cushing syndrome, or polycystic ovary syndrome, among other causes.

Because the list of disorders associated with secondary amenorrhea is even longer than the list associated with primary amenorrhea (Table 22–9), the initial evaluation is very broad until the differential diagnosis is narrowed by the results of physical examination, history, and initial radiographic and laboratory studies. The laboratory workup for secondary amenorrhea begins with measurement of hCG to rule out pregnancy. Hypothyroidism and hyperprolactinemia should next be ruled out as the cause of disease by measuring TSH and prolactin. Patients with normal TSH and prolactin should be evaluated for gonadotropic function by measuring LH and FSH. Estrogen or a progestin stimulation test may be helpful in cases where the cause of amenorrhea is unclear. In women with hirsutism or other signs of hyperandrogenism, a total or free testosterone and DHEA-S should be measured. An elevation of DHEA-S points to an adrenal origin as a cause for the hirsutism. An elevation in testosterone suggests either an adrenal or an ovarian source, or an androgen-secreting tumor outside the adrenal and ovaries.

hCG, human chorionic gonadotropin.

GH has secretory spikes, with a half-life of about 20 minutes, which typically occur several hours after meals and exercise. The secretion of GH also rises after the onset of sleep and reaches a peak in deepest sleep.
CHAPTER 22  The Endocrine System

the release of GH from the pituitary. Growth hormone-releasing hormone (GHRH) stimulates GH release from the pituitary, and somatostatin (also known as growth hormone-inhibitory hormone [GHIH]) inhibits GH release. The larger influence on the release of GH by the pituitary is the inhibitory action of somatostatin. To promote growth, GH in the circulation binds to target tissues, mostly cartilage, bone, and other soft tissues. GH predominantly exerts its growth effects by stimulating insulin-like growth factors (IGFs) that are produced in the liver and other tissues. Because of its homology to insulin, GH directly affects lipid, carbohydrate, and protein metabolism. IGFs, previously known as somatomedins, also have multiple effects on growth promotion and metabolism. There are a number of IGFs. Unlike most other peptide hormones, IGFs circulate in the blood in a complex with plasma-binding proteins, known as insulin-like growth factor-binding proteins (IGFBPs). The complex physiology of GH signaling is shown in Figure 22–11.

Laboratory Tests

Growth Hormone

Most of the assays for GH are performed using serum, because the concentration of GH in urine is approximately 0.1% of that in serum. Human GH exists in the pituitary gland and in the circulation as a heterogeneous mixture of isoforms. The presence of GH variants in serum can lead to discrepant results among the different assays for GH, although most commercially available GH assays are now calibrated against WHO-standardized materials. Even if the assay problems did not exist, a single random GH measurement is not usually clinically informative because of the diurnal variability and pulsatile secretion of GH by the pituitary gland. Serum concentrations between pulses in healthy individuals are extremely low and may not even be detectable. Provocative tests aimed at testing its stimulation or suppression are usually required to establish GH abnormalities (Table 22–10). A commonly used stimulation test to assess the adequacy of GH secretion is the insulin tolerance test, which produces a transient hypoglycemia to provoke

**FIGURE 22–11** The regulation of growth hormone (GH) secretion. [+]: Stimulation; [−]: inhibition.
GH release. One GH suppression test involves the ingestion of an oral glucose load, which in healthy individuals suppresses GH secretion from the pituitary.

**Insulin-like Growth Factors**

IGF-1 circulates in much higher concentrations in plasma than GH, and its secretion is not episodic or diurnal. Therefore, IGF-1 is a good screening test of suspected GH abnormalities and for monitoring therapy in patients with known abnormalities. A single elevated IGF-1 in patients with signs and symptoms of GH excess should be followed with an oral glucose tolerance test (GH suppression testing). A single decreased IGF-1 should prompt treatment in patients with known growth deficiency or an insulin tolerance (or other GH stimulation) test in patients suspected to have GH deficiency. There are marked differences in IGF-1 concentration between adults and children. Therefore, it is very important to establish age-specific reference intervals.

**Growth Hormone Excess—Acromegaly and Gigantism**

**Description**

The most common cause of excess GH production is a chromophobe adenoma of the pituitary gland. A prolonged excess of GH results in an overgrowth of the skeleton with acral enlargements, as well as overgrowth of the soft tissues, and these are found in 100% of the patients with this condition. In adults, this condition is known as acromegaly. Because GH has an action on the cartilaginous portion of the bone, GH excess in children before long bone growth is completed results in gigantism.

**Diagnosis**

The most important requirement for diagnosis of GH excess is a demonstration of unsuppressible GH secretion. Because of the episodic secretion of GH, as many as 10% of patients with active acromegaly have random serum GH concentrations that are within the normal reference interval. An elevated IGF-1 measurement prompts provocative testing and correlates with disease severity. Serum GH concentrations are typically not suppressed by oral glucose loading in patients with acromegaly. Their serum GH concentrations show either no change from baseline or a slight increase. Healthy individuals show marked suppression after oral glucose load. The serum IGF-1 concentration, even as a random test, correlates with the clinical severity of acromegaly better than the test for glucose-induced GH suppression.

**Growth Hormone Deficiency**

**Description**

A deficiency of GH may be congenital or acquired. Children who have inadequate GH production or action will not grow to full height. It should be noted that growth retardation is typically not usually caused by GH deficiency. However, children with growth retardation or reduced growth velocity with no obvious explanation should be evaluated for a GH deficiency. In children,
causes of GH deficiency include anatomic damage to the pituitary or hypothalamus, isolated GH deficiency in the pituitary, and a combination of pituitary hormone deficiencies from a variety of causes. In adults, the most common causes of GH deficiency are pituitary irradiation and a pituitary adenoma that impairs GH secretion. Since adults are usually at full height, GH deficiency does not change growth velocity. However, it is associated with cardiac abnormalities, increased cholesterol, reduced muscle mass, energy, and bone density, and lean body mass. GH replacement in deficient adults may increase lean body mass and bone density, and reduce cholesterol.

**Diagnosis**
After ruling out other causes of short stature, patients with signs and symptoms of GH deficiency can be screened by measuring IGF-1; if low, the diagnosis of GH deficiency requires the demonstration of a persistently low GH concentration in 2 different provocative stimulation tests (Table 22–10). The provocations for GH release that can be used include vigorous exercise, deep sleep, and treatment with glucagon, L-DOPA, insulin, or arginine. Insulin and glucagon are the most commonly utilized agents.

**Prolactin/Anterior Pituitary**
**Physiology and Biochemistry**
Prolactin is secreted by the anterior lobe of the pituitary gland. It is a polypeptide with 198 amino acid residues that structurally resembles GH, and is secreted by lactotrophic cells in the anterior pituitary. Prolactin production is regulated by stimuli from the hypothalamus, but unlike most other anterior pituitary hormones, its release is primarily controlled by inhibition rather than by stimulation (see Figure 22–12). The primary negative stimulus to the pituitary that limits prolactin secretion is provided by dopamine. There are various stimulatory factors for prolactin release, along with the inhibitory compounds. One stimulatory factor is TRH. Another mechanism to increase prolactin release from the pituitary is to decrease the inhibitory effect of dopamine. A number of medications inhibit dopamine action. Prolactin secretion, like that of several other anterior pituitary hormones, is episodic. Concentrations of prolactin are at their lowest at midday, with the highest values shortly after the onset of sleep. The major physiologic stimulus

**FIGURE 22–12** The regulation of prolactin secretion. [+] Stimulation; [–] inhibition.
for prolactin release is suckling of the breast in lactating women. This results in a rise in maternal plasma prolactin concentrations within minutes to initiate milk production. Prolactin controls the initiation and maintenance of lactation only if the breast tissue is appropriately primed by estrogens and other hormones for ductal growth, development of the breast lobular and alveolar system, and the synthesis of specific milk proteins.

**Laboratory Tests**

**Prolactin**

As with GH, there is molecular heterogeneity in prolactin with multiple isoforms, which can lead to discrepant results among the immunoassays. A high-molecular-weight isoform, macroprolactin, is a clinically inactive species that contains large aggregates of prolactin with immunoglobulins. It is recognized by many commercial immunoassays and can be the source of hyperprolactinemia. Physicians should check for macroprolactin by precipitation or size exchange chromatography in any patient with an elevated serum prolactin of unknown origin. The best serum specimen is one that is collected 3 to 4 hours after the subject has awakened. It is important to collect the specimen after an overnight fast, when the patient is still resting, because emotional stress, exercise, ambulation, and protein ingestion all elevate the baseline prolactin level. Multiple sampling may be necessary because of the episodic secretion of prolactin.

**Hyperprolactinemia**

**Description.** There are many causes for an elevated prolactin concentrations, one of which is a pituitary adenoma. Pregnancy, chronic renal failure, chest wall trauma, primary hypothyroidism, and a host of medications can also elevate prolactin levels. Elevation of the serum prolactin concentration is associated with many different signs and symptoms. In women, these include anovulation, with or without menstrual irregularity, and amenorrhea. Men with prolactin-secreting pituitary adenomas often present with oligospermia, impotence, or both.

**Diagnosis.** A patient with a prolactin-secreting pituitary adenoma generally has a higher elevation of serum prolactin than someone with hyperprolactinemia from a different cause. Because so many medications can provoke prolactin release, and medications are the most common cause of an elevated serum prolactin level, a medication history is very important. Noteworthy medications that can elevate the serum prolactin level include estrogens, dopamine antagonists such as haloperidol, histamine receptor-blocking agents such as cimetidine, and tricyclic antidepressants.

**Hypoprolactinemia**

**Description and Diagnosis.** This condition is not detected unless a woman fails to lactate postpartum. A low prolactin level in a woman in this setting is consistent with hypoprolactinemia.

**Antidiuretic Hormone (ADH)/Posterior Pituitary**

**Physiology and Biochemistry**

The posterior pituitary secretes oxytocin and ADH, also known as arginine vasopressin. ADH is a small peptide with 9 amino acids. Oxytocin has a similar structure. Release of hormones from the posterior pituitary into the circulation occurs with stimulation of selected neurons. In the circulation, ADH and oxytocin are usually not bound to carrier proteins.

ADH secretion is triggered by elevated plasma osmolality as well as decreased blood volume or blood pressure (Figure 22–13). Even a small increase in osmolality causes stimulation of ADH release to increase water retention and decrease the plasma osmolality toward normal. ADH induces increased permeability of water in the renal collecting ducts leading to increased water reabsorption and concentration of urine. ADH is also known as vasopressin because it binds to receptors on smooth muscle cells that induce vasoconstriction, thereby increasing the blood pressure and volume. Other nonosmotic stimuli such as pain, stress, sleep, exercise, and a variety of pharmacologic compounds induce ADH secretion from the posterior pituitary as well. Negative feedback for ADH release is provided by atrial natriuretic peptide (ANP). With an increased circulating blood volume or a decreased osmolality, ANP concentrations increase,
inducing decreased ADH release. The osmolality of the plasma also impacts the thirst center to coordinate oral intake of water and conservation of water in the kidney.

**Laboratory Tests**

**Antidiuretic Hormone**

ADH can be measured using an immunoassay. It is a temperature-sensitive peptide, and plasma testing should be performed within 24 hours after collection. Freezing the specimen stabilizes it for many months. A single ADH measurement is not diagnostic, and the result should be assessed in the context of the results of serum and urine osmolality testing.

**Serum and Urine Osmolality**

Serum and urine osmolality are measured using a freezing point depression osmometer. Serum osmolality can be estimated by various mathematical formulas using sodium, glucose, and BUN concentrations.

**Water Deprivation Test**

Patients with suspected diabetes insipidus (DI) are deprived of all fluids until urine osmolality is constant for 3 hours and/or plasma osmolality is greater than the normal range. Once constant, serum osmolality and ADH are measured. ADH is then administered and urine osmolality and volume are measured at 1 and 2 hours post administration.

**Polyuria**

**Description.** A deficiency of ADH or resistance to the action of ADH results in the failure of the renal tubules to reabsorb water and, as a result, an increased amount of water is lost into the urine. Because urine output is dependent on fluid intake, a normal urine output cannot be defined. However, whenever there is more than 2.5 L of urine generated per day, an investigation for a cause of polyuria is usually indicated.

Polyuria can occur from 3 main causes. The first is deficient production of ADH, as occurs in central diabetes insipidus. The second cause for polyuria is deficient ADH action in the kidney. The third cause of a polyuric state is excessive water intake.
thirst center is abnormal, and there is excess water loss into the urine. Congenital disorders of the pituitary or neoplastic diseases, neurological surgery, head trauma, ischemia, and autoimmune disorders account for most of the cases of central DI.

The second cause for polyuria is insensitivity of renal tubules to ADH. This is known as nephrogenic DI and it can be caused by any damage to the renal tubules that impairs water reabsorption.

The third cause of a polyuric state is excessive water intake. This is known as psychogenic or primary polydipsia. In rare cases, hypothalamic disease can affect the thirst center and induce polydipsia. There are also many medications that can affect the thirst center and cause polydipsia.

Diagnosis. The differential diagnosis of a polyuric state requires measurements of serum and urine osmolality, serum sodium, urine volume, and plasma ADH concentrations. The first step is to document that polyuria exists by establishing that the urine volume exceeds 2.5 L per day. Glycosuria must be excluded as a cause of the polyuria, as hyperglycemia with diabetes mellitus is a common cause of polyuria. Patients with central DI have hypernatremia, high plasma and low urine osmolality, and low or inappropriately normal plasma ADH level because the pituitary is unable to secrete ADH. Patients with nephrogenic DI also have a high serum sodium and osmolality and a low urine osmolality with polyuria and polydipsia. Because of renal insensitivity, they have a normal to high plasma ADH because the hypothalamus generates excess hormone in an attempt to compensate for high plasma osmolality. Patients with primary polydipsia usually have hyponatremia and normal serum and low urine osmolality, with an appropriately low-normal plasma ADH concentration (Table 22–11). The diagnosis of DI can be confirmed with a provocative test called the water deprivation test. After dehydration, a urine osmolality greater than plasma with a low ADH, followed by an increase in urine osmolality of more than 10% in 1 hour following ADH administration, indicates central DI. The excess ADH promotes reabsorption of water by the kidney, resulting in a decreased urine volume and an increased urine osmolality. A high ADH after dehydration, followed by a failure to increase urine osmolality after ADH administration, suggests nephrogenic DI because the defect in this disorder is a failure of the kidney to respond to ADH. After water deprivation, patients with primary polydipsia will have urine osmolality higher than serum and show no increase in urine osmolality after ADH administration.

**Syndrome of Inappropriate Antidiuretic Hormone Secretion (SIADH)**

**Description**

SIADH is an autonomous, sustained synthesis and release of ADH in the absence of stimuli. Thus, plasma ADH concentrations are inappropriately increased relative to the osmolality. There are a number of known causes of SIADH; it is common among patients with pulmonary or central nervous system disorders. Another cause is production of ADH by a malignant tumor, especially a small cell carcinoma of the lung. In addition, there are a number of medications that stimulate the production of ADH. The patient’s blood volume is modestly expanded, and serum sodium concentrations may be decreased along with serum osmolality. SIADH is a commonly encountered cause of hyponatremia in hospitalized patients.

**Diagnosis**

Patients with SIADH usually have a low serum osmolality, a urine osmolality greater than that of serum, and an elevated urine sodium concentration (Table 22–11). There are many causes for SIADH is an autonomous, sustained synthesis and release of ADH in the absence of stimuli. Thus, plasma ADH concentrations are inappropriately increased relative to the osmolality.
hyponatremia other than SIADH, including congestive heart failure, renal insufficiency, nephrotic syndrome, liver cirrhosis, and treatment with medications that stimulate ADH secretion. SIADH is not often assessed by measurement of plasma ADH because the ADH level is not usually necessary to make the diagnosis.

**NEOPLASTIC DISORDERS**

**Multiple Endocrine Neoplasia**

**Description**

MEN is a syndrome most often inherited as an autosomal dominant trait. The MEN syndromes are associated with hyperplasia or tumors in multiple endocrine glands at the same time. There have been many recent advances in the understanding of the genetic basis of the different types of MEN.

- **Multiple endocrine neoplasia type-1 (MEN 1; Wermer syndrome)**—MEN 1 syndrome involves hyperplasia or neoplasms in 1 or more of the following: the parathyroid gland, the pancreatic islet cells, or the anterior pituitary in patients with a known family history of MEN 1. In the absence of a family history of the syndrome, however, at least 2 or more of the primary MEN 1 tumor types must be involved for a diagnosis of MEN 1. The hormonal presentation of MEN 1 is highly variable because the pituitary and the pancreatic islet cells in neoplastic states can secrete many different hormones. Although the prevalence is reported to be 20 to 200 per million live births, it is likely to be greatly underestimated because the clinical expression of MEN 1 varies and often presents with mild symptoms. Patients with MEN 1 usually present in the fourth decade of life. MEN 1 has been linked to a gene mutation in the MEN 1 (menin) gene on chromosome 11.

- **MEN 2 (Sipple syndrome)**—The most commonly found abnormality in the MEN 2 syndrome is medullary thyroid carcinoma that occurs in over 95% of patients with MEN 2. Pheochromocytoma develops in over 50% of patients with MEN 2, and parathyroid hyperplasia or adenoma produces hyperparathyroidism in 15% to 30% of patients with MEN 2. MEN 2 includes 3 major phenotypes. Over 90% of the cases of MEN 2 are MEN 2A that includes risk of developing MTC, pheochromocytoma, and hyperparathyroidism. The familial cases of MEN 2A are most often diagnosed in the third or fourth decade of life. In MEN 2B, parathyroid disease is rare and there are separate developmental abnormalities such as ganglioneuromatosis and marfanoid habitus, in addition to pheochromocytoma and MTC. MEN 2B generally presents 10 years earlier than MEN 2A. It accounts for approximately 5% of all MEN 2 cases. MEN 2B is usually recognized early in life. The child with MEN 2B has a characteristic facial appearance with a failure to thrive, mucosal neuromas, and constipation or diarrhea due to the ganglioneuromatous in the gut. The diagnosis can be made conclusively by demonstrating the presence of a mutation in the RET proto-oncogene. The RET proto-oncogene product is a receptor tyrosine kinase that transmits growth and differentiation signals. The third form of MEN 2 is familial MTC in the absence of pheochromocytoma and hyperparathyroidism. This disorder has a later onset than MEN 2A or MEN 2B and usually has a good prognosis. The most common clinical presentation in the patient with medullary carcinoma is a mass in the neck. The diagnosis is most often made by histopathologic review of a specimen acquired by fine needle biopsy.

**Diagnosis**

Because of the variety of hormonal abnormalities in MEN 1, many different assays are needed to demonstrate hyperplasia or neoplasms of the parathyroid, pancreatic cells, and/or anterior pituitary, all of which may be involved in MEN 1. Genetic mutations in the coding sequence of the RET proto-oncogene are found in the vast majority of patients with MEN 2 (both MEN 2A and MEN 2B) and those with isolated familial MTC. Any first-degree relative of a patient carrying an MEN-associated mutation should also be evaluated. Onset of C-cell hyperplasia and malignancy of the thyroid in patients with a known RET proto-oncogene mutation should be monitored by measuring calcitonin and routine thyroid ultrasounds (see the section “Thyroid”).
**Carcinoid Tumors**

**Description**

Carcinoid tumors are the most common of the endocrine tumors. They are generally found in the wall of the gastrointestinal tract, but also can be found in the pancreas, rectum, ovary, and lung. Tumors originating from the primitive foregut include carcinoid of the bronchus, the stomach, the first portion of the duodenum, and the pancreas. These tumors often secrete 5-hydroxytryptophan, histamine, and other peptides. Carcinoid tumors originating from the primitive midgut are those found in the second portion of the duodenum, the jejunum, the ileum, and the ascending colon. These tumors secrete serotonin, also known as 5-hydroxytryptamine, and other peptides. They are associated with the development of carcinoid syndrome, which is characterized by cutaneous flushing, gastrointestinal hypermotility with diarrhea, heart disease, bronchospasm, myopathy, and increased skin pigmentation. Tumors originating from the primitive hindgut include those of the transverse colon, descending colon, and rectum. These tumors are typically silent because they are usually nonsecretory. Therefore, functioning carcinoid tumors are more likely to be detected if they secrete a compound that has biological activity. The serotonin-secreting carcinoid tumors arising from the primitive midgut or foregut are the ones most often detected. Silent carcinoid tumors are most often discovered incidentally at surgery for other disorders in the gastrointestinal tract. Patients with silent carcinoid tumors may have vague abdominal pain that is either undiagnosed or attributed to irritable bowel syndrome.

**Diagnosis**

Serotonin (5-hydroxytryptamine) is transported in the blood by platelets. It is metabolized to 5-hydroxyindoleacetic acid (5-HIAA). 5-HIAA is quantitatively the principal metabolite of serotonin, and the majority of it is excreted into the urine and can be used as an indicator of serotonin production. Patients with serotonin-secreting carcinoid tumors of midgut origin usually have markedly elevated concentrations of urinary 5-HIAA. If there is a borderline concentration of 5-HIAA in a random or 24-hour urine specimen, a repeat collection should be made with an avoidance of foods or medications that might elevate the 5-HIAA concentrations. Only when the 5-HIAA is normal or borderline is the measurement of serotonin needed to document the diagnosis. Platelets contain almost all the serotonin found in the blood and for that reason, the serotonin is measured in whole blood (with platelets) or in platelet-rich plasma.

Functioning foregut tumors may also be detected by the urinary 5-HIAA assay, even though they secrete 5-hydroxytryptophan rather than serotonin. Urinary 5-HIAA is elevated because the 5-hydroxytryptophan released from these tumors is converted to serotonin in other tissues and is subsequently metabolized to 5-HIAA. In addition, urine histamine is generally elevated in patients with functioning foregut carcinoid tumors because these tumors (in contrast to midgut carcinoids) usually produce histamine.

types, subtypes, and expected test results,
277–278
von Willebrand factor, 10
assays, 34
major roles, 275
W
Waldenström macroglobulinemia, 326
Warfarin (coumadin), 2, 8, 259, 266, 287,
288, 304
WDHHA syndrome, 376
Werner syndrome, 464
Western blot, 42
White blood cell (WBC)
disorder, approach to patient with, 318
disorders associated with impaired
function, 337
Chediak–Higashi syndrome, 337
chronic granulomatous disease, 337
myeloperoxidase deficiency, 337
nonneoplastic proliferation, 320
nonneoplastic proliferation, 319
Wilson disease, 360
Wiskott–Aldrich syndrome, 279, 280, 306
Women amenorrhea, laboratory evaluation
of, 457
X
X-linked agammaglobulinemia (XLA), 74
laboratory evaluation, 75
Y
Yersinia enterocolitici, 93, 139, 309
Z
Zinc protoporphyrin (ZPP), 181, 237, 240
Zollinger–Ellison syndrome, 375
Zymogens. See Proenzymes
